ABSTRACT

We study the problem of efficiently scheduling a computational 5 DAG on multiple processors. The majority of previous works have 5 developed and compared algorithms for this problem in relatively 5 simple models; in contrast to this, we analyze this problem in a 5 more realistic model that captures many real-world aspects, such as 5 communication costs, synchronization costs, and the hierarchical 5 structure of modern processing architectures. For this we extend the well-established BSP model of parallel computing with non-uniform 5 memory access (NUMA) effects. We then develop a range of new 5 scheduling algorithms to minimize the scheduling cost in this more 5 complex setting: several initialization heuristics, a hill-climbing local search method, and several approaches that formulate (and 5 solve) the scheduling problem as an Integer Linear Program (ILP). 5 We combine these algorithms into a single framework, and conduct 5 experiments on a diverse set of real-world computational DAGs to 5 show that the resulting scheduler significantly outperforms both 5 academic and practical baselines. In particular, even without NUMA 5 effects, our scheduler finds solutions of 24% – 44% smaller cost on 5 average than the baselines, and in case of NUMA effects, it achieves up to a factor 2.5× improvement compared to the baselines. Finally, 5 we also develop a multilevel scheduling algorithm, which provides 5 up to almost a factor 5× improvement in the special case when the 5 problem is dominated by very high communication costs. 5

The definitive version (extended abstract) was published in the 36th ACM Symposium on Parallelism in Algorithms and Architectures (SPAA 2024), https://doi.org/10.1145/3626183.3659972.

1 INTRODUCTION 7

The optimal scheduling of complex computational workloads on 8 multiple processors has been extensively studied since the early 8 days of computing. As the different subtasks in a computation usually have precedence constraints between them (one subtask can 8 only be started after another one has been finished), the computations in these applications are often modeled as Directed Acyclic 8 Graphs (DAGs), with the directed edges representing these dependencies 8

Besides the structure of the DAG representing the computation, 9 the other main ingredient of a scheduling problem is the machine 9 model assumed. DAG scheduling has been studied in a very wide 9 range of models in the past decades, differing in e.g. the numbers and types of processors, the modelling of communication costs, or 9 other properties of the system such as synchronization or preemption. However, for arbitrary computational workloads (i.e. general 9 DAGs), finding an optimal or close-to-optimal schedule is already 9 very challenging in the simplest possible models, e.g. with uniform 9 processors and very simple models of communication (or even no 9 communication costs at all) 9

<u>Due to this_previous research has mostly focused on variants</u> 10 of the scheduling problem where either the set of input DAGs or 10 the scheduling model is heavily restricted or simplified. Theoretical 10 work has almost exclusively studied very restricted models, where 10 <u>it is still manageable to analyze approximation algorithms or hard-</u> 10 ness results: however, these models are usually far from realistic. 10 Experimental research has developed several scheduling heuristics 10 <u>based on natural ideas such as locality</u> that <u>generally deliver good</u> 10 empirical results in simpler models; however, these heuristics are 10 completely impervious to the parameters of real-world systems. 10 and hence it is unclear how their performance carries over to more 10 <u>complex models. On the practical side, the parallel computing com-</u> 10 munity has developed more sophisticated models, such as the Bulk 10 Synchronous Parallel (BSP) or the LogP model, that capture many aspects of a real-world system; however, due to their complexity. 10 these models have mostly been used for developing and analyzing parallel implementations of concrete computations (i.e. specific 10 DAGs), instead of general computational tasks. As such, while each 10 of these directions offers valuable insight, we still lack a proper 10

[12, 18, 30, 35, 38]. On the other hand, the topic of developing ap-

understanding of how to devise efficient scheduling algorithms for arbitrary DAGs in a realistic machine model 10

Our goal in this paper is to develop and analyze scheduling all gorithms for this more general case: we consider the scheduling problem for general DAGs, in a model that captures many of the most important aspects of real computations. In particular, we begin from the BSP model which already accounts for communication volume and latency, and we extend this with a simple model of non-uniform memory access (NIJMA) effects, which also have a defining role in modern manycore architectures. We then develop a framework of scheduling algorithms in this more realistic model, and compare this against several state-of-the-art scheduling algorithms from previous research and from applications, on a set of DAGs representing a wide range of actual computational tasks.

Our first contribution in the paper is a database of computational 12 DAGs, which offers a diverse benchmark to evaluate different sched- 12 uling algorithms in the future. Then in terms of algorithms, we 12 first present some heuristic methods to develop initial schedules 12 (similar to heuristics from previous works, but tuned towards our 12 realistic model). We then develop more advanced scheduling algorithms that take a different approach: instead of making heuristic 12 decisions based on e.g. locality, they consider the actual cost of 12 each solution in our complex model (with all its parameters), and 12 12 directly optimize for minimizing this cost. In particular, we develop (i) a local search algorithm that iteratively improves a solution by 12 making small modifications to a schedule as long as this decreases 12 its total cost, and (ii) several different ways to model the problem 12 as an Integer Linear Program (ILP), and use an ILP solver to find 12 (sub)schedules of small cost. Finally, we also present a multilevel 12 scheduling approach that is superior in the case when our schedul- 12 ing problem is substantially dominated by communication costs. 12

Unsurprisingly, our more complex algorithms require notably 13 more running time than lightweight heuristics, and hence their 13 study is not viable on very large graphs. On the other hand, in 13 the domain where they are applicable, our results show that they 13 significantly outperform the baseline heuristics. In particular, even 13 without NUMA effects, our scheduler achieves a cost reduction of 13 32%-51% compared to a simpler, and 13%-40% compared to a more 13 sophisticated baseline, depending on the number of processors 13 and the parameters of the model, on DAGs up to 10 000 nodes 11 and the parameters of the improvement is even larger: 48%-17% to the simpler, and 27%-58% to the stronger baseline, or with 13 the multilevel algorithm, even up to 79% (i.e. almost a factor 5× 13 improvement) to the stronger baseline in some cases. This shows 13 that in realistic scheduling models, our approach can indeed return 13 drastically better solutions than the baseline algorithms 13

2 RELATED WORK 14

Different variants of the DAG scheduling problem have been studied thoroughly since the 1960s. In the first decades, research has mostly focused on very simple settings that either do not consider communication costs (motivated by the PRAM model) or only capture it as a fixed delay independently of communication volume. In terms of theoretical results, scheduling is known to be already NP-hard in these simple models, and on special subclasses of DAGs 15

proximation algorithms in these models is still extensively studied 15 in recent years [16, 20–22]. 15 On the experimental side, researchers have developed a range 16 of different scheduling heuristics, and evaluated their performance 16 empirically. Recent surveys [41] have classified these heuristics 16 into two groups: list-based [2, 13, 26, 32, 36] and cluster-based 16 [14, 17, 42] methods. To our knowledge, there is very little previous 16 work on evaluating these heuristics in more realistic models (with 16 the exception of [27], which is discussed separately below). 16 On the more practical side, BSP is one of the prominent models of 17 parallel computing, and has been studied extensively from various 17 perspectives [4, 23, 34, 39, 40]. The BSP model accounts for several 17 important real-world aspects such as communication volume and 17 latency but it conveniently captures all these in a relatively simple 17 cost function; as such, it is also used in various applications via 17 the BSPlib library and its implementations [11, 43, 44]. However, 17 most of the previous works on BSP (and on similar models with 17 more parameters, such as LogP [6]) focus on the scheduling of 17 specific DAGs that describe a concrete computation [8, 24, 25] 17 One exception to this is a recent theoretical work that studies the 17 computational complexity of BSP scheduling for given subclasses 17 of DAGs, and also presents a naive ILP formulation to capture the 17 BSP scheduling problem on general DAGs [28] 17 The impact of NUMA in an algorithmic context has also been 18 studied before on e.g. different variants of the (hyper)graph parti- 18 tioning problem [9, 29, 33] 18 Numerous other variants of the scheduling problem have also 19 been studied extensively, e.g. with separate deadlines for nodes or 19 with node duplication [3, 19]. 19 The closest result our work is the work of Ozkaya et al. [27]. 20 who conduct a similar experimental study with the same goal of 20 analyzing sophisticated scheduling algorithms in a more realistic 20 model. Our work differs from their approach in several aspects. 20 Firstly the work of [27] introduces a custom model (named duplex 20 single-port model) that only extends classical scheduling models 20 with communication volume; in contrast to this, our work considers 20 BSP, a well-established parallel computing model in both theory 20 and practice which also captures further aspects such as latency 20 and we further extend this with NUMA effects. Moreover, while the 20 main idea of [27] is to extend modern list schedulers with a acyclic 20 partitioner, we take an entirely different approach, and focus on 20 methods that aim to directly minimize the cost function (such as 20 local search and ILP representations). 20

3 PROBLEM DEFINITION AND BACKGROUND 21

3.1 Preliminaries 22

We assume that our computation is represented by Directed Acyclic	23
Graph (DAG) $G(V, E)$. The nodes of the DAG correspond to subtasks	23
or operations we need to execute, and the directed edges correspond	23
to dependencies between these operations: an edge from node u	23
to node v implies that the execution of u has to be finished before	23
the execution of v begins, because the output of u is required as an	23
nput for v . We denote the number of nodes by n . 23	

Besides the structure of the DAG, our computation is described by two parameters for each node v: the computation weight w(v) 24

(also called *work weight*) is the amount of time required to execute operation v on a processor, and the *communication weight* c(v) is the amount of communication required to send the output of v to 24 another processor (e.g. its size in bytes). These weights can differ significantly between the different nodes, so they are both crucial 24 to include in our model. Note that we consider the communication weight c(v) to be a property of each node of the DAG (in contrast to e.g. [27], where it is assigned to the edges). For simplicity, we assume that node weights are integers 24

3.2 The BSP model 26

The BSP model assumes that the computational steps are organized into so-called *supersteps*. Each superstep consists of the following 26 two phases 26

- (1) Computation phase: each processor can execute an arbitrary 27 amount of computation, but no communication is allowed 27
- (2) Communication phase: processors can communicate any 27 number of values to each other, but no computation happens, 27

Intuitively supersteps correspond to larger batches of computations that are executed consecutively on a single processor without any interruption for communication. Dividing the computations into such batches is often beneficial in practice, since the communication often comes with a significant overhead that is independent of the number of communicated values, due to e.g. synchronization or network initialization. 28

Our computing architecture in BSP is described by three parameders: the number *P* of processors available, the time cost *a* of sending a single unit of data between processors, and a fixed overhead cost *t* (called the *latency*) incurred by each superstep. 29

When applying the BSP model to DAG scheduling our schedule 30 must respect the dependencies described by the edges of the DAG 30 This means that a node v can only be computed on processor p 30 in superstep s if the output values from all its direct predecessors 30 are already present on p: that is, they were either computed on 30 p in an earlier (or the same) superstep, or they were sent to p by 30 another processor before superstep s. In the communication phases 30 a processor p can send the output value of any node v if it is already 30 present on p, to any other processor(s) 30

Formally a BSP schedule of a DAG consists of (i) an assignation and supersteps $\pi: V \to \{1, ..., P\}$ and supersteps $\pi: V \to \mathbb{N}$, and (ii) a communication schedule Γ , i.e. a set of 4-tuples $\{v, p_1, p_2, s\}$, indicating that the output of node v is sent from processor p_1 to processor p_2 in the communication phase of superstep $\{v, v\}$ and $\{v\}$ and $\{v\}$ is a sent from processor $\{v\}$ and $\{v\}$ in the communication phase of superstep $\{v\}$ and $\{v\}$ is a sent from $\{v\}$ and $\{v\}$ in the communication phase of superstep $\{v\}$ and $\{v\}$ in the communication phase of superstep $\{v\}$ is a sent from $\{v\}$ and $\{v\}$ in the communication phase of superstep $\{v\}$ in the communication phase of supers

- For each edge (u, v) of G, in case of $\pi(u) = \pi(v)$, we must have $\tau(u) \le \tau(v)$, and in case of $\pi(u) \ne \pi(v)$, we must have an entry $(u, p_1, \pi(v), s) \in \Gamma$ for some processor p_1 and some superstep $s < \tau(v)$ 32
- For each $(v, p_1, p_2, s) \in \Gamma$, we must either have $\pi(v) = p_1$ 32 and $\tau(v) \le s$, or we must have another $(v, p', p_1, s') \in \Gamma$ 32 with s' < s 32

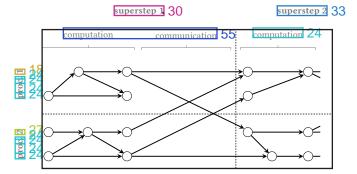

Figure 1: Example BSP scheduling of a DAG. 34

An example for a BSP scheduling of a DAG is illustrated in Figure 33

1. In the computation phase processors 1 and 2 execute 4 and 5 33 operations (nodes), respectively; then in the communication phase processor 1 needs to send one value to processor 2, while processor 33 needs to send two values to processor 1 (to make these available on the given processors for superstep 2). After this, the computation 33 phase of superstep 2 can begin 33

3.3 Cost in BSP 36

Another advantage of BSP is that in contrast to classical models, 36
BSP assigns a simple cost metric to each superstep, and the total 36
time required (i.e. total cost of a schedule) can be obtained by simply 36
summing up the costs of the individual supersteps, 36

In the computation phase of each superstep, the subtasks assigned to each processor are executed by the processors simultaneously: as such the cost of a computation phase is defined as the maximum work assigned to any processor in the superstep, i.e. 37

$$C_{work}(s) = \max_{p \in \{1,\dots,P\}} \sum_{\substack{\pi(v) = p \\ \tau(v) = s}} w(v)$$

On the other hand, communication costs are measured by the socalled *h-relation* metric, where the cost of a communication phase is determined by the maximum amount of data sent or received by any processor. That is, the send cost and receive cost, respectively of processor p in superstep s is 38

$$C_{send}(p,s) = \sum_{\substack{(v,p_1,p_2,s_1) \in I \\ p_1 = p \\ s_1 = s}} 45 \quad c(v)$$

$$C_{rec}(p,s) = \sum_{\substack{(v,p_1,p_2,s_1) \in I \\ p_2 = p \\ s_1 = s}} 45 \quad c(v)$$

and the communication cost of superstep s is 39

$$C_{comm}(s) = \max_{p \in \{1,\dots,P\}} \max \left(C_{send}(p,s), C_{rec}(p,s) \right)$$

The total cost of superstep s is then the sum of the work communidation, and latency costs, defined as 40

$$C(s) = C_{work}(s) + g \cdot C_{comm}(s) + \ell$$

and the cost of the whole schedule is obtained by simply summing 41 up C(s) for all the supersteps. 41

For more details on the properties and the different variants of 42 this model, we refer the reader to [28] 42

3.4 NUMA effects 43

BSP already captures communications more realistically than most classical models. However, one significant drawback of BSP is that it assumes a uniform communication cost between any pair of processors. In contrast to this, today's computing architectures very often exhibit a hierarchical structure: each processor has multiple cores, each machine has multiple processors, and maybe multiple machines are connected over a network. This hierarchical structure results in a non-uniform memory access setting, where the cost of sending a piece of data heavily depends on the concrete pair of processing units that communicate: sending a value between two cores on the same processor is relatively low, whereas sending the same data over the highest level of the hierarchy (e.g. over the hierarchy (e.g. over the highest level of the hierarchy (e.g. over the hierarchy (e.g. over the highest level

This asymmetry between the processors is often a defining aspect of the scheduling problem in practice. Due to this, we also extend 45 the BSP model which such NUMA effects, and further analyze 45 the impact of this in our experiments. The BSP definition above is straightforward to extend to this setting: if the cost λ_{p_1,p_2} of communicating a single unit of data is known for each pair of processors (p_1, p_2) , then we can simply add λ_{p_1,p_2} as a further factor in the formulas defining $C_{send}(p, s)$ and $C_{rec}(p, s)$ above. The values λ_{p_1,p_2} then become further input parameters of the problem, we can specify them either directly for each pair of processors or implicitly through a hierarchy. Note that the default case of 45 uniform communication costs corresponds to a choice of $\lambda_{p_1,p_2} = 1$ for $p_1 \neq p_2$, and $\lambda_{p_1,p_2} = 0$ for $p_1 = p_2$.

3.5 Problem definition 47

Altogether, the input of our problem is (i) a DAG with node weights 47 w(v) and c(v), and (ii) a machine description with the parameters 47 P, q and ℓ , and possibly λ_{p_1,p_2} for all pairs of processors p_1 , p_2 . Our q_1 do is to find the best valid schedule in the BSP model, minimizing the total cost q_1 and q_2 do in the problem is (ii) a DAG with node weights q_2 and q_3 and q_4 and q_4 and q_4 and q_5 and q_6 are in the parameters q_1 and q_2 are in the parameters q_4 and q_5 are in the parameters q_4 and q_5 and q_6 are in the parameters q_6 and q_6 and q_6 are in the parameters q_6 and q_6 are in t

We sometimes also discuss the *communication scheduling* subproblem of optimizing Γ when π and τ are already fixed, i.e. sorting the necessary communication steps into the given communication steps into the given communication the necessary communication steps into the given communication steps into the given communication steps into the given communication steps in the necessary communica

4 SCHEDULING ALGORITHMS 50

We now describe our scheduling algorithms in the BSP model. Due to space constraints, we only outline the main ideas behind each algorithm: we discuss them in more detail in Appendix A. The pipeline combining the algorithms is discussed later in Section 6.

4.1 Baselines 51

In order to evaluate our approach, we use the following baseline 52 schedulers for comparison: 52

•	Cilk: this is a simple and yet efficient scheduling heuristic	53
	[5]: different variants of the same work-stealing approach	53
	are widely used in many of today's prominent parallel pro-	53
	gramming libraries and frameworks. While Cilk was origi-	53
	nally not defined on DAGs, it is easy to adapt to this case] 53
	Intuitively, Cilk maintains a stack of ready tasks for each	53
	processor to work on, and if a processor is idle (its stack is	53
	empty), it "steals" a subtask from the bottom of a (randomly	53
	chosen) other processor's stack. We use Cilk to represent	53
	the baseline from the practical/application side. 53	

- be BL-EST and ETF: recent comparison studies have found that the best scheduling algorithms are list-based schedulers to be schedulers the best scheduling algorithms are list-based schedulers to be schedulers to be most efficient in earlier experiments, they have also already been adapted to a setting with communication volume [27]. When scheduling the next node both BL-EST and ETF assign the node to the processor that offers the earliest start time, based on previous assignments and necessary communication steps. While BL-EST always selects the next node based on the longest outgoing path ETF selects the node with the earliest starting time.
- HDagg: a more recent and more advanced state-of-the-art scheduler is the HDagg algorithm of Zarebavani et. al. [46]. 53

 HDagg is presented and analyzed in [46] for the specific purpose of speeding up SpTRSV computations; however, it is in fact a scheduling algorithm that can be applied to any computational DAG. Moreover, HDagg considers a very similar scheduling model to ours, sorting the nodes of the DAG into so-called wavefronts (essentially equivalent to supersteps), and minimizing the amount of communication between these wavefronts. Our experiments also show that HDagg consistently outperforms both BL-EST and ETF. Due to this, HDagg is a very fitting baseline for our work from the academic side, 53

Besides list-based schedulers clustering is also a prominent method of designing state-of-the-art heuristics; however previous 54 work has found that this approach is consistently outperformed by BL-EST and ETF in models with communication cost [27]. 54

Note that Cilk, BL-EST and ETF return a "classical" schedule 55 where nodes are assigned to concrete time steps: such a schedule 55 can be naturally adapted to BSP and organized into supersteps, by adding a superstep barrier (closing the current computation phase) 55 whenever communication is required. In contrast to this, schedules 55 returned by HDagg are already in the appropriate format. 55

4.2 Initialization heuristics 56

In order to develop an initial BSP schedule, we use the following 57 heuristic methods: 57

BSPg: A BSP-tailored greedy algorithm that consecutively assigns nodes to processors when processors become idle.
 Generally we only allow assigning a node v to processor to if this is possible without ending the computational phase of the current superstep s, i.e. if we can ensure that all of v's predecessors are already available on p by superstep 58

s (that is, they were either computed on processor p or	30
in an earlier supersten). In case of multiple possible node	
assignments to a processor tie-breaking is done with a	
heuristic that aims to minimize communication costs in the	30
future. Once we cannot assign further nodes to at least half	
of the processors without a communication requirement.	30
the computation phase of the current superstep is closed.	30
and a next superstep is started 30	
Courses A different and decomposed that in each stan formal	
 Source: A different greedy approach that in each step forms a new superstep from the next layer of source nodes in 	28
the DAG. As a preprocessing step in the beginning, the	
algorithm uses a simple rule to cluster the original source	20
nodes of the DAG. Then in each superstep, it applies a	28
round-robin-based approach to assign the current source	20
nodes to processors, considering the nodes in a decreasing	28
order according to $w(v)$ to ensure the load balancing of	
work costs between processors. Besides the current source	20
nodes, the algorithm occasionally also adds some of their	28
successors to the current superstep, if this requires no extra	
communication 28	
 ILPinit: We also apply an ILP-based initialization heuristic 	
that divides the nodes into smaller batches according to a	
topological order, and consecutively finds a schedule for	
each batch separately (given the already-selected partial	
schedules on previous batches), using an ILP-formulation	
of the subproblem. This approach also provides good initial	
schedules, but it requires drastically more running time	58
than the heuristics above. 58	
Note that the above heuristics only assign the nodes to proces-	59
sors and superste <u>ns,</u> i.e. they only define π and τ . The required	59
communication steps Γ are then derived from these separately af-	
terwards, sim <u>ply following a lazy communication schedule where</u>	
every required value is sent in the last possible communication	59
phase, immediately before it is needed 59	
4.3 Local search algorithm 12	
Another ingredient of our framework is a hill climbing local search	12
method (denoted HC) that begins from an initial solution (that is	
an already found, valid BSP schedule), and attempts to make small	
improvements to this solution as long as this is possible. i.e. until	12
either a local minimum is found where none of the potential modi-	
fication steps result in an improvement, or until a predefined time]
limit is reached 12	
For each local improvement step, given a node v that is currently	
assigned to processor p and superstep s, we consider all the alterna-	
tive schedules where v is assigned to any other processor $p' \neq p$ in	
superstep s, or v is assigned to any processor in supersteps $(s-1)$	
or (s + 1), with the assignments of all the other nodes unchanged.	
We consider all such modification steps (for every node v), provided	02
that they yield a valid BSP schedule with smaller total cost 62	60
Note this algorithm needs to be aware of the cost of the modified	
solution after each potential improvement step. Recalculating this	63

we apply a range of sophisticated data structures to store the cur-

rent schedule, and use these to efficiently query (and update) the 63

cost change incurred by each potential improvement step, without	63
having to consider nodes and supersteps that are unaffected by this	
modification. 63	
Besides this algorithm, we also apply a separate, similar hill climb-	6
ing method for the communication scheduling subproblem (denoted	
HCcs), which only tries to modify the communication schedule; that	
is, it checks whether any communication step $(v, p_1, p_2, s) \in \Gamma$ can	64
be replaced by some other (v, p_1, p_2, s') such that the schedule is	64
still valid and has lower cost 64	

ILP-based approach

As our most sophisticated approach, we represent the BSP schedul-
ing task as an ILP problem, and apply a state-of-the-art open-source 66
ILP solver (CBC, see [7]) to find a low-cost schedule. We use several 66
techniques to express (parts of) the scheduling problem as an ILP 66
• ILPfull: A naive representation of BSP scheduling as an 67
ILP problem has already been described before in the work 67
of [28], but only analyzed from a theoretical perspective, 67

- This formulation captures the entire problem as a single ILP 67 and hence it requires a very high number of variables. Due 67 to this, even with sophisticated ILP solvers, this approach 67 is only feasible for very small DAGs in practice 67
- ILPpart: In order to handle larger DAGs, we develop a par- 67 tial ILP formulation as a more advanced iterative improve- 67 ment method. In particular, given a starting BSP schedule 67 and two superstep indices $s_1 \leq s_2$, we define a partial ILP 67 that only reorganizes the supersteps between s_1 and s_2 ; that 67 is, we only consider nodes v that are currently assigned to 67one of the supersteps in the interval $[s_1, s_2]$, and try to re- 67 assign these differently to any processor and any superstep 67 in $[s_1, s_2]$, with the rest of the schedule unchanged. This 67 gives a significantly smaller ILP that essentially only scales 67 with the number of supersteps between s_1 and s_2 and the 67 number of nodes assigned to these supersteps. Given this 67 partial ILP formulation, we can then divide the range of 67 supersteps into disjoint intervals, and then repeatedly use 67 this approach to further polish each part of our schedule. 67
- ILPcs: We also devise and implement a separate ILP representation for the communication scheduling subproblem, 67 i.e. the scheduling of communication steps Γ when π and τ 67 are already fixed. This problem has a significantly smaller 67 degree of freedom, hence the ILP solver can often return 67 reasonably good solutions for it on the entire DAG, even 67 for DAGs of larger size. If we already have a BSP schedule 67 with a specific π and τ we can use this ILP formulation 67 to find a more optimal scheduling of the communication 67 steps, hence resulting in a lower total cost. 67

When using an ILP solver in practice, we can achieve much 68 better results by starting the solver from a good initial solution: 68 this is provided by the initialization and local search algorithms 68 discussed before. 68

4.5 Multilevel approach 71

While our algorithms above perform well in general, we have found that they are often unable to find good solutions in problems dominated by communication costs, e.g. when the weights c_v or some of the parameters g, ℓ or λ_{D_1,D_2} are excessively large. Intuitively speaking, in this case, a reasonable solution always needs to assign a well-connected cluster of nodes to the same processor, in order to avoid too much communication. In contrast to this, both our initialization heuristics and our local search algorithms attempt to (re)schedule single nodes separately, so they do not perform well in this case, $\frac{1}{100}$

In order to address this problem, we also present a *multileve* 71 scheduling algorithm, inspired by the multilevel approach that 71 consistently provides state-of-the-art results for hypergraph partitioning and other problems [15, 31, 33, 37]. When adapted to our 71 scheduling problem, the three main steps of the multilevel paradigm 71 are as follows: 71

- (1) **Coarsening** the DAG iteratively into smaller and smaller

 DAGs_which (ideally) retain most of the structure of the
 original DAG. In our case, we do this by repeatedly contracting a selected edge (u, v) of the DAG into a single node. The
 contracted edges are chosen in each step such that (i) the
 graph still remains a DAG after the contraction, and (ii) we
 prefer edges (u, v) where the total work weight w(u)+w(v)
 is small, but the communication weight c(u) is large.
- (2) Solving the BSP scheduling problem in our coarsened DAG 72 with the algorithms discussed before. The coarsened DAG 72 is not only much smaller (and hence more viable for our 72 algorithms) but also naturally ensures that larger clusters 72 of nodes are assigned to the same processor and superstep. 72
- (3) Uncoarsening and refining this schedule iteratively. That 72 is in each step, we undo the next few contraction steps in a 72 reverse order, thus obtaining a slightly larger DAG, and we extend our current assignment π and τ to the newly uncontracted nodes. We then execute a few iterative improvement 72 steps (using our local search algorithm) to ensure that the 8 schedule is further refined to fit the more delicate structure 74 of the more uncoarsened DAG. 72

Note that this approach is somewhat similar to the idea of combining an acyclic DAG partitioner with list schedulers in the work of [27]. However, while most of the experiments in [27] focus on 73 creating a few (at most 4·P) larger partitions, our coarsening phase sorts the DAG into a larger number of smaller clusters. Even more importantly, instead of applying a partitioning directly, our algorithm coarsens the DAG in a step-by-step fashion, since the gradual 73 refinement steps in the uncoarsening phase are the key element of 73 the multilevel approach 73

5 COMPUTATIONAL DAG DATABASE 74

Besides the algorithms, we also present a collection of DAGs that 75 represent a diverse set of real-world computational tasks, and 75 hence offer a large and realistic benchmark to evaluate our sched-75 uling algorithms. Our computational DAG database is available at 75

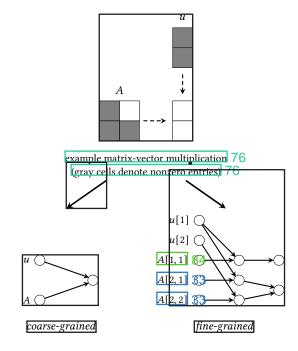

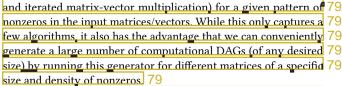

Figure 2: Coarse-grained and fine-grained DAG representa- 77 tion of a simple matrix-vector multiplication.

https://github.com/Algebraic-Programming/HyperDAG_DB_and 75 its details are discussed in Appendix B. 75

Most of the DAGs in our database correspond to computations in 76 some algebraic form: they are derived either directly from algebraic 76 computations, or from computations in various other areas that 76 can naturally be expressed in algebraic form. Since these kinds of 76 computations typically work with matrices and vectors, there are 176 two natural ways to represent them as computational DAGs. In the 176 coarse-grained representation, each matrix or vector corresponds to (the output of) a single node in our DAG. In the 176 fine-grained 176 representation, we also attempt to capture the internal structure of 176 matrices/vectors: in this case, each nonzero entry in a matrix/vector 176 is represented by (the output of) a separate node in our DAG. An 176 example for the two representations is shown in Figure 2.

To obtain coarse-grained DAGs, we extended the C++ Graph-78
BLAS framework from [45] with a so-called hyperDAG backend, which automatically extracts the structure of a given computation 78
while the computation is running. This allows us to conveniently obtain a DAG representation for the wide variety of algorithms 78
implemented in GraphBLAS, such as the conjugate gradient and 78
biconjugate gradient stabilized methods, the pagerank algorithm 78
label propagation, k-nearest neighbors, and many more. Since many 78
of these algorithms are iterative methods, we can obtain different 78
computational DAGs with this technique if we run the given algorithms for a predefined number of iterations, or until convergence. 78

To obtain fine-grained DAGs, the extension of GraphBLAS would 78 be significantly more technical, so we follow a different approach: 79 we produce a simple tool that synthetically generates the computational DAG corresponding to four concrete algorithms (conjugate 79 gradient, k-nearest neighbors, sparse matrix-vector multiplication 79

As a technical detail, we note that in line with some recent works 80 [29, 31], the DAGs in our database are represented in a hypergraph format (with hyperedges containing a node and all of its direct 80 successors), but these are easy to convert back into a DAG format.

6 EXPERIMENTAL SETUP 81

For our experiments, we implemented the algorithms described 82 above. Since the CBC ILP solver has a convenient Python interface we implemented the ILP-based methods in Python, and the rest 82 of the algorithms in C++. Our experiments were conducted on a 82 workstation equipped with Intel Core i9-10900 CPU at 2.80GHz and 82 62.5 GiB of RAM 82

The up-to-date version of our scheduling framework is available 83 at https://github.com/Algebraic-Programming/OneStopParallel. We 83 note that the current version of this scheduling tool has been significantly extended and upgraded since our experiments. For reproducibility, the version of the implementation used for the experiments, as well as the computational DAG database and the data 83 from our experiments, are available in the repository at [1] 83

In order to tune our algorithms, we first ran some preliminary experiments on a small training set of 10 fine-grained computational 84 DAGs, with their sizes ranging from n = 15 to n = 2000, and with 84 BSP parameter combinations from $P \in \{4, 8, 16\}$ and $q \in \{1, 3, 5\}$, and a fixed $\ell = 5$. These initial experiments (discussed in Appendix C) showed that ILPinit is only competitive when we have very few processors, while it is rather time-consuming; as such, we chose 84 to only apply ILPinit for P = 4, 84

We also observed that the CBC solver can usually return reladitively good solutions whenever the number of variables in the ILP 67 representation is below approximately 4 000; we have used this as 67 our guiding principle in ILPpart, choosing to extend the superster 67 interval [s₁, s₂] until the number of variables in the resulting ILP 67 exceeds 4 000. Besides this, we also noted that the ILP solver rarely 67 returns any reasonable solution above 20 000 variables: in this case 67 even the preprocessing heuristics of CBC can exceed an 1-hour time 67 limit. Due to this, we only attempt the naive ILPfull approach 67 from [28] in very small DAGs, where the estimated number of 67 nartially due to the fact that our work uses an open-source ILP 67 solver; with today's more powerful commercial ILP solvers, the 67 same approach could be applied to a significantly higher number 67 of variables 67

For our main experiments, we construct 4 different test sets of DAGs, labeled tiny, small, medium and large, with *n* in the ranges 86 [40, 80], [250, 500], [1000, 2000] and [5000, 10000], respectively. We generated a set of fine-grained instances with different properties (varying matrix sizes and iterations to produce some "wider" and some "deeper" DAGs), covering these intervals. This resulted in 12 DAGs in the tiny dataset, and 21 in the remaining datasets (the tiny set is smaller since only a few parameter options can generate

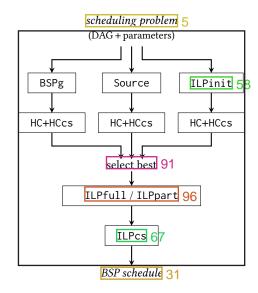

Figure 3: Summary of our scheduling framework. 89

so small DAGs). We further added to each of these datasets all the	
coarse-grained instances in the DAG database which has n in the	86
same interval 86	
Besides the machine parameters in the training set, we exper-	87
iment with different values of $\ell_{\underline{i}}$ and also with different NUMA	
parameters. Our NUMA settings each correspond to a binary tree	87
<u>hierarchy over the P leaf nodes, with the communication cost in-</u>	87
creasing by a specific factor Λ over each new level, with choices	87
of $\Delta \in \{2, 3, 4\}$. For example, in case we have $P = 8$ and $\Delta = 3$, then	87
the communication costs from the first processor are $\lambda_{1,2} = 1$, then	87
$\lambda_{1,p} = 3$ for $p \in \{3, 4\}$, and $\lambda_{1,p} = 9$ for $p \in \{5, 6, 7, 8\}$. 87	
Finally, we also create a smaller dataset with DAGs of size $n \in$	
[50000, 100000], called the huge dataset, in order to observe how	88
our simpler algorithms scale to even larger DAGs. We do not study	88
the ILP-based methods here, since they would be far too time-	88
consuming in this case. 88	
For the experiments, we combine our algorithms in the pipeline	91
shown in Figure 3. We begin by running the initialization heuristics	91
to obtain different initial schedules. We then improve each of these	
separately with the local search methods (since running HC+HCcs is	
rather inexpensive), and then select the best schedule obtained this	
way. We then use the ILP-based methods: we begin with ILPfull	_
in the few cases where the number of variables is below 20 000. If	91
ILPfull was not applicable, or its solution was not shown to be	
optimal by the ILP solver, we apply the further ILP-based methods	91
ILPpart and ILPCs. 91	
When ILPfull is applicable, we assign a time limit of 1 hour	92
to this. We allow 5 minutes for HC+HCcs and 5 minutes for ILPcs	
(although these algorithms rarely time out), and 3 minutes for each	92
iteration of ILPpart. 92	
When using the multilevel approach, the pipeline begins with	
a coarsening step (see Figure 4). We then apply the scheduling	
framework shown in Figure 3, and finally refine the DAG in the end	9:

Since the coarsened versions of the DAGs only provide an imprecise 93

estimation of the real amount of communication required in the 93

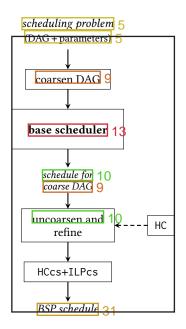

Figure 4: Summary of our multilevel framework. Base scheduler refers to the pipeline in Figure 3 (without ILPcs). 13

original DAG, we explicitly run the communication scheduling 24 algorithms (HCcs and ILPcs) after the uncoarsening phase. 24

7 EMPIRICAL RESULTS 10

On any given problem instance, we evaluate the scheduling algorithms by the ratio between the cost returned by our algorithm and the baselines. In each dataset/experiment, we then aggregate these ratios through a geometric mean (this is more accurate for ratios than the average) to obtain a metric of the overall improvement achieved by our algorithms (with respect to the baselines) on the dataset. The results in our figures are normalized with respect to the cost of the Cilk baseline.

As for our remaining baselines, we found that ETF and BL-EST 11 are consistently outperformed by HDagg, so out of these, we only 11 include HDagg in our figures and tables. The schedules achieved by 11 ETF and BL-EST are briefly discussed in Appendix C. 11

For simplicity besides the baselines, our diagrams only show the 5 best initialization method (labelled Init), the cost after applying 5 HC+HCcs (labelled HCcs), and the final cost after all the ILP methods 5 (labelled ILP). More details on the results (e.g. improvements by 5 each separate ILP method) are also provided in Appendix C. 5

7.1 Without NUMA 13

We first run our schedulers on the tiny, small, medium and large datasets, for $P \in \{4, 8, 16\}$, $q \in \{1, 3, 5\}$ and $\ell = 5$, without NUMA Over the combination of all parameters and datasets, the mean cost ratio between Cilk and our scheduler is 0.56, while the cost ratio between HDagg and our scheduler is 0.76. This means that our approach indeed returns schedules with significantly lower cost than the baselines: it achieves a 44% cost reduction compared to Cilk, and a 24% reduction compared to HDagg. 13

A detailed analysis also shows that this improvement factor de- 13 pends on the choice of parameters and dataset. In particular, Table 1 13 shows the cost reduction with respect to the baselines, separated 13 according to q and P (left), and q and the dataset (right). The table 13 shows that the improvement ranges from 32% to 51% compared to 13 Cilk, and from 13% to 40% compared to HDagg. We can observe 13 that the difference between our scheduler and the baselines consis- 13 tently grows larger with higher a: this is because communication 13 costs become more dominant, but these are not (accurately) con- 13 sidered by the baselines. The same holds for larger P values, since 13 this often result in more data that needs to be communicated in 13 a schedule. As for the size of the dataset, the tables suggest that 13 the improvement compared to Cilk is mostly unaffected, while 13 the improvement compared to HDagg becomes smaller for large 13 datasets. This is likely because our schedulers come with a higher 13 time complexity, and hence they do not scale as well as HDagg; 13 improving this property is a strong candidate for our future work. 13 However, we note that even in this cases, our schedules are still 13 consistently better than those returned by HDagg. 13

In order to understand the role of each of our different algorithmic ingredients, we also show the cost ratios achieved by the algorithms (compared to Cilk), separated for different values of *g*, 10 in Figure 5. The figure shows that while the initialization heuristics are already much more efficient than the baselines, the local search and ILP methods both achieve some further improvement. In Appendix C, we also discuss the role of the different algorithms in more detail; for instance, the ILP-based methods tend to result in a more significant improvement on the smaller datasets, and only a minor improvement for larger DAGs 10

We also considered the effect of the latency parameter ℓ on our schedules separately (see Appendix C for details). Our experiments show that the difference between our scheduler and the baselines also grows for larger values of ℓ , although not as rapidly and as consistently as for the parameter q. This is in line with our previous observations, since the latency ℓ is essentially a different kind of communication cost which is once again not considered by the baseline methods 13

For our preliminary experiments on the huge dataset, we only applied the non-ILP methods from our algorithmic framework. 13
BSPg and Source, followed by HC+HCcs with a larger time limit of 30 minutes. Even for this larger dataset, our scheduler achieves an improvement ranging from 15% to 41% compared to Cilk, and a more marginal improvement from 6% to 13% compared to HDagg (details again in Appendix C). This demonstrates that our general approach also scales reasonably well to computational DAGs with 13 up to 100 000 nodes 13

7.2 With NUMA effects 5

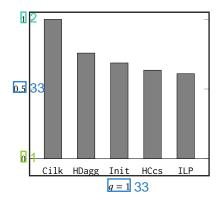

When we extend the BSP model with NUMA effects, the improve-
ments achieved by our scheduler are even larger. On average over
all the parameters $P \in \{8, 16\}$ and $\Delta \in \{2, 3, 4\}$, our method provides
a 60% improvement compared to Cilk and a 43% improvement
compared to HDagg. 5

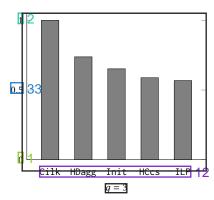

The results in this setting show an even stronger dependence on P and the NUMA multiplier A: the improvement consistently grows in both of these parameters, as also illustrated in Figure 6 13

Table 1: Results achieved by our scheduler (in a NUMA-free setting), restricted to given values of g, P and given datasets. The two numbers in each cell show the reduction in cost compared to Cilk and HDagg, respectively. 13

	q = 1	<i>q</i> = 3	g = 5 33
P=4	32% / 20%	40% / 24%	44% / 26% 96
P = 8	40% / 21%	45% / 25%	45% / 25% 96
P = 16	43% / 18%	49% / 26%	51% / 30% 96

	q = 1	q = 3	q = 5 33
tiny	32% / 26%	40% / 35%	43% / 40% 97
small	38% / 22%	44% / 30%	46% / 32% 97
medium	43% / 17%	47% / 21%	49% / 23% 97
large	41% / 13%	46% / 14%	48% / 15% 97

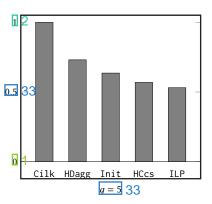

Figure 5: Performance comparison of Cilk, HDagg and our scheduling algorithms without NUMA effects, for values $g \in \{1, 3, 5\}$.

(let us ignore the ML column in the figure for now). In particular, for the case of P=8 and $\Delta=2$, the improvement is only 48% compared to Cilk and only 27% compared to HDagg. On the other hand, when we have P=16 and $\Delta=4$, the schedule returned by our algorithm has a 71% lower cost than Cilk, and a 58% lower cost than HDagg. We also show the concrete improvements for each case in a numerical format in Table 2 13

Note that the case of P=16 and $\Delta=4$ amounts to a very significant improvement in scheduling cost: more than a 3× factor
for Cilk, and almost a 2.5× factor for HDagg. Moreover, since Δ is
often indeed large in practice, one might argue that this is the most
realistic among our parameters for capturing today's computing architectures. Altogether, this suggests that our approach may indeed
be able to provide significantly better schedules for many relevant
applications.

We also point out that the local search and ILP methods also 5 become much more important ingredients in this NUMA setting 5 achieving a notably larger further improvement than in the case 5 without NUMA 5

7.3 Multilevel scheduling 5

Finally, we analyze our multilevel scheduling method, which was designed particularly for the case when communication costs are very high. For instance, in our previous setting for the highest choice of $\Delta = 4$, we have seen that our scheduler is notably better than the baselines. However, this is only their relative performance in fact, both our scheduler and the baselines perform rather poorly in this setting, and even the solutions returned by our scheduler 5

Table 2: Cost reduction achieved by our base scheduler in a setting with NUMA effects, for different values of P and Δ , 13 compared to Cilk and HDagg, respectively, 13

	$\Delta = 2$	$\Delta = 3$	$\Delta = 4$ 33
P = 8	48% / 27%	55% / 35%	61% / 42%
P = 16	57% / 36%	67% / 51%	71% / 58%

are often barely better (or in several cases, in fact, even worse) than 13 the trivial solution of assigning all nodes to the same processor 13 and superstep. Our multilevel algorithm, on the other hand, is 13 able to find good solutions even in this rather challenging setting 13 consistently beating this trivial baseline. 13

The cost ratio of the multilevel method to the other schedulers is also shown in Figure 6 for different values of P and Λ . For completeness, we also show the improvement values in numerical format in Table 3. The figure shows that when communication costs are high (e.g. if we have $\Lambda = 4$. or if we only have $\Lambda = 3$ but P = 16. and hence there are NUMA coefficients as high as $\lambda_{1.16} = \Delta^{\log_2 P - 1} = 27$ in our binary hierarchy), then the multilevel method is able to considerably outperform our base scheduler. For the highest choice of P and Λ , the multilevel algorithm finds solutions that on average provide a further factor $2\times$ improvement to our base scheduler. Altogether, this amounts to a very significant, almost a factor $5\times$ cost reduction, even compared to HDagg. 13

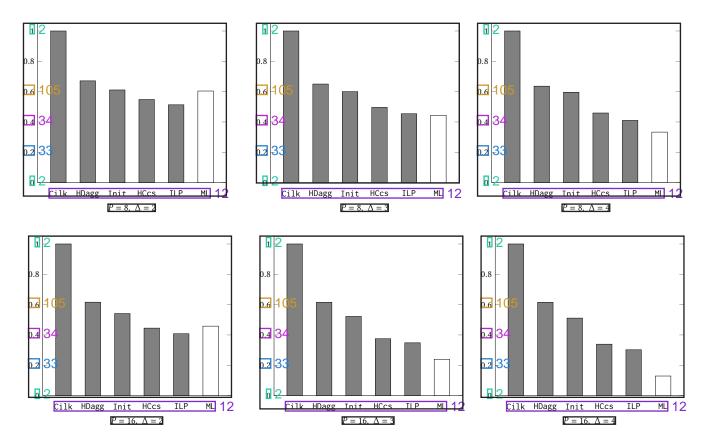

Figure 6: Performance comparison of Cilk, HDagg and our scheduling algorithms with NUMA effects, for different $P \in \{8, 16\}$ and different NUMA increase factors $\Delta \in \{2, 3, 4\}$. The multilevel approach (ML) is shown separately at the end. This specific figure only covers the small, medium and large datasets, since tiny is too small to coarsify with ML; however, in general, our improvement factors in Section 7.2 and Appendix C also include tiny.

Table 3: Cost reduction achieved by the multilevel algorithm 5 with NUMA effects, for different P and Δ , compared to Cilk and HDagg. 5

	$\Delta = 2$	$\Delta = 3$	$\Delta = 4$ 33
P = 8	40% / 10%	56% / 32%	67% / 48% 9
P = 16	54% / 26%	76% / 61%	87% / 79%

However, while the multilevel algorithm achieves a large further 5 improvement for high communication costs (large Λ and/or P), on 5 the other hand, for the case of Δ = 2, the figure shows that ML is 5 clearly inferior to our base scheduler. Similarly, if we revisit the set 5 ting of Section 7.1 without NUMA effects, the multilevel approach 5 provides notably weaker solutions in general than our base scheduler (see Appendix C for details). This suggests that our multilevel method is indeed a specialized tool, which is useful mostly when our problem is dominated by high communication costs. However, 5 we note that our algorithm is a relatively simple implementation of 5 this multilevel scheduling idea; we believe that with some further 5

work, the same approach could become an efficient tool for any choice of parameters 45

Our results show that if we consider a more detailed and more 13

8 CONCLUSION

realistic model of the scheduling problem, then applying a range of advanced algorithms can significantly outperform classical scheduling heuristics like Cilk or HDagg. 13

Unsurprisingly, the main drawback of these more advanced algorithms is that they come with a notably higher running time. 13

More specifically, BSPg and Source take a similarly small amount of time as the baselines, but the remaining algorithms are more time-consuming: HC+HCcs and Multi typically take between 1-2 seconds to 1-2 minutes on our DAGs, and the ILP-based methods 13 take even longer, hence each individual ILP is capped at a few minutes. While the running times of these initial implementations can still be reduced significantly, in general, it is inevitable that this more complex direct optimization approach requires much more 13 time than lightweight heuristics 13

However, while this running time is certainly a limitation of our 13

work, the benefits from the higher-quality schedules can still make 13 our approach useful in various applications e.g. 13

- when the same computation needs to be executed many times, possibly with different inputs, 20
- when the computation can be captured in a coarse-grained way by relatively small DAGs, but possibly still with large node weights, 19
- in areas such as machine learning, where this scheduling time may still be negligible compared to the execution of the computation itself (e.g. the training of a neural network).

Furthermore, even in areas where our approach is not directly applicable in practice, our algorithms still provide crucial insight on 13 the performance of the baseline heuristics; our solutions with much 13 smaller cost prove that the schedules returned by these baselines 13 are often very far from the optimum. Besides this, our results also 13 highlight the fact that many real-world aspect, such as communication volume and NUMA costs, are critical to include in our model, 13 otherwise the algorithms may return solutions that are significantly 13 suboptimal

There are many natural directions for future work, i.e. towards finding schedules of even lower cost in BSP, or in even more detailed models. In particular, we note that most of the ingredients in our algorithmic framework are relatively simple applications of a specific technique, used as prototypes to demonstrate the feasibility of our technique, used as prototypes to demonstrate the feasibility of our tentire approach. As such, each of these algorithmic building blocks can be further improved into or replaced by more sophisticated methods: we could apply e.g. more complex local search techniques that also attempt to escape local minima, or more efficient ILP formulations for our problems, or more advanced methods for the coarsening and refining phase of the multilevel method. We also point out that our experimental results were achieved with an open-source ILP solver: simply employing one of today's more powerful commercial ILP solvers could already significantly improve these results without any changes to the framework itself 10

ACKNOWLEDGMENTS

We would like to thank Benjamin Lozes for his valuable help with applying the HDagg algorithm as a baseline in our work. 13

A DETAILS ON OUR ALGORITHMS 10

This section provides a more detailed discussion of our different algorithms. Recall that the implementations of these algorithms that we used in the experiments (together with our database and the data from the experiments) are available at [1], while a more up-to-date version of our scheduling framework can be accessed at 10 https://github.com/Algebraic-Programming/OneStopParallel

Our algorithms can be run via a set of Python scripts, which allow 13 us to configure the files or directories containing the input problems 13 to solve, and several parameters of the solving process. Besides this 13 user interface, the Python scripts also contain the implementations 13 of our ILP-based methods, and are responsible for invoking the 13 CBC ILP solver 12

The remaining C++ code (the Cilk, ETF and BL-EST baseline algorithms and their conversion to BSP, the BSPg algorithm, the HO and HCcs local search methods, and the ingredients of the multilevel framework) are available in the file simple_schedulers.cpp. The only exception is the Source heuristic, which is implemented in a separate file named second_heuristic_weights_cluster.cpp. 13
These two C++ files are automatically compiled and invoked by the Python scripts

Finally we provide the Python scripts required for running and 11 evaluating HDagg separately, since these are independent from our own implementations, and they also require the HDagg library as 10 an external dependency [46]]

As a general remark on our algorithms, we also note that some our simpler methods only return an assignment of nodes to processors and supersteps, but not a concrete communication schedule. These algorithms implicitly assume that the corresponding Γ is the lazy communication schedule defined by the assignment, where every value is sent directly and in the last possible superstep; that is, if a node v has a direct predecessor u, and $\pi(v) \neq \pi(u)$, then we have $\pi(u) = \pi(u) = \pi(v) = \pi(u) = \pi(v) = \pi(u) =$

A.1 Baseline methods 20

The main idea of the Cilk work-stealing scheduler was already outlined before: it is a greedy algorithm where every ready task 20 (i.e. node with all of its predecessors already computed) is added to the "ready stack" of one of the processors. Whenever one of the processors become idle (it finishes computing a node), it takes the topmost ready task from its own stack, and begins the execution of this node. If the processor's stack is empty it selects another processor with a non-empty stack (uniformly at random among these processors) and starts executing the node at the bottom of this stack, also removing the node from the stack. This ensures that no processor is idle whenever there is a ready node.

We note that originally, Cilk was not defined on DAGs, but 11 instead on processes that spawn further subtasks during execution 11 In this original setting, each spawned subtask is added to the top 11

of the stack of the processor executing the parent process. In contrast to this original setting our DAGs do not have parent-child 13 relationships between the given nodes. To adapt the algorithm to 13 DAGs, we use a very similar rule: whenever the execution of the 13 last direct predecessor of a node v is finished, if this happens on 13 processor v, then v is added to the top of processor v's stack 13

As for BL-EST and ETF, we refer the reader to the work of [27] 5 for more details. We note that our baseline implementation for both of these algorithms corresponds to the versions described in [27] which is already extended with the concept of communication 5 volume (but not with latency or NUMA effects, since these are new 5 in our model). In case have NUMA effects, we compute the Earliest 5 Start Time (EST) in these baseline algorithms by considering the average coefficient of the communication cost over all pairs of processors, and multiplying c(v) with this number when considering the required communication steps. Note that an extension of the EST computation with NUMA factors would also be possible, to obtain a version of these baselines that is more specialized towards our more realistic model; however, we leave the investigation of 5 this approach to future work.

We also note that Cilk, BL-EST and ETF assign nodes to concrete points in time. This can be naturally converted into a BSP schedule by sorting it into supersteps iteratively: if some of the nodes are already assigned to supersteps 1, ..., (s-1), we can find the earliest point t in time when our classical schedule begins executing a node v such that (i) v is not yet assigned to a superstep, (ii) v has a direct predecessor v_0 also not yet assigned to a superstep, and (iii) our schedule has $\pi(v) \neq \pi(v_0)$. This implies that the next computation phase can last at most until time t; hence we assign all nodes that are executed before step t to superstep s, and we continue with this procedure for superstep (s+1).

Finally, HDagg is a more sophisticated algorithmic baseline, which 11 directly develops a BSP-like schedule, sorting the nodes of the DAG 11 into supersteps (called 'wavefronts'), and then distributing nodes 11 among processors in each wavefront. The algorithm strives to en- 11 sure both a balanced workload among processors in a supersten 11 and a reduced amount of inter-processor communication between 11 the supersteps. For more details of the algorithm, we refer the 11 reader to [46]. Note that this algorithm was originally developed 11 (and analyzed) for the specific purpose of speeding up SpTRSV com- 11 putations, i.e. solving sparse linear systems defined by a triangular matrix. However, the method is in fact a general DAG scheduling algorithm that can be applied to any computational DAG; it is even 12 analyzed in [46] using DAG terminology. That is, after a topological 11 ordering the adjacency matrix of any DAG becomes lower trian- 11 <u>gular, and by artificially adding an edge from each node to itself 11</u> (i.e. setting the main diagonal of the matrix to 1, thus ensuring 11 it is non-singular), we obtain an SpTRSV problem where the de- 11 pendency DAG derived from the matrix is identical to our original 11 computational DAG. As such, the schedule returned by HDagg for 10 this matrix directly corresponds to a schedule for our original DAG 11 in the BSP model 11

Since the original implementation of HDagg from [46] is openly available, we directly apply this in our experiments: we convert our computational DAG into the required triangular matrix format we use the example script from the HDagg library to output the 15

p in the current superstep. This allows us to avoid creating further 159

supersteps unnecessarily, by slightly relaxing the principle that 159

only the source nodes are assigned in each superstep. 158

```
Algorithm 1 Summary of the BSPg heuristic 146
                                                                            has predecessors on a single processor p in the current superstep. 153
                                                                            then v is added to a set ready, of that processor, signaling that _{153}
  superstep \leftarrow 0.157
  endStep ← False 157
                                                                            processor p is already allowed to execute v in the current superstep. 153
                                                                            Whenever a task is finished and some processor p becomes free, the \sqrt{153}
   finishTimes \leftarrow \{0\} 157
                                                                            are assigned a new node to execute (based on rules discussed below). 153
  free[p] \leftarrow True \text{ for all } p 157
                                                                            if this is still possible without closing the current computation phase. 153
  while there are still unassigned nodes do 157
                                                                            i.e. there are still nodes that have all their direct predecessors on b
     if endStep = True and finishTimes = 0 then 157
                                                                            or in earlier supersteps. When half of the processors become idle 153
        ready_p \leftarrow \emptyset for all p \mid 157
                                                                            (they cannot be assigned new nodes), the computation phase is 153
       ready_{all} \leftarrow ready
       superstep \leftarrow superstep + 1
                                                                            closed, and a following superstep is started, where all the nodes in 153
                                                                            ready<sub>all</sub> are now available to each processor. 153
       endStep ← False 157
                                                                              When selecting a new node to compute for a processor <u>n</u>, we 154
       finishTimes \leftarrow \{0\} 157
                                                                            employ the following method (named ChooseNode in our pseu- 154
    end if
                                                                            docode). We first attempt to choose from the nodes in ready, that 154
     t \leftarrow \text{earliest time from } finishTimes 157
                                                                            are only available for <u>p</u>, and if this is empty, we choose from the set 154
     for all nodes v that finish at t do 157
                                                                            ready_{all} available to all processors. From both sets, we use the same 154
       free[\pi(v)] \leftarrow True
                                                                            tie-breaking rule that attempts to reduce communication costs, as- 154
       for all out-neighbors u of v do 154
                                                                            signing a score metric for each node v in the set, and selecting the 154
          if u's in-neighbors are all finished then 157
                                                                            node with the highest score. For this score, we consider all direct 154
             ready \leftarrow ready \cup \{u\}
                                                                            predecessors u of v, and if either u or one of its direct successors is 154
             if \forall (u_0, u) \in E we have either \pi(u_0) = \pi(v) or \tau(u_0) < \tau(u_0)
                                                                            already assigned to p, then we increase the score of v by \frac{c(u)}{\text{outdeg}(u)},
             superstep then 154
               ready_{\pi(v)} \leftarrow ready_{\pi(v)} \cup \{u\} 157
                                                                            where outdeg(u) is the outdegree of u. Intuitively, this can be un-
            end if 154
                                                                            derstood as an estimator for the importance and probability of the 154
         end if 177
                                                                            fact that we can assign u and all its direct successors to \underline{v}, thus 154
       end for 177
                                                                            not having to communicate u at all. If c(u) is high, then sending 154
    end for 177
                                                                            u results in a higher cost, and thus more important to avoid; if 154
    if endStep = False then 177
                                                                            outdeg(u) is small, then there is a higher chance that we can in-
                                                                 ∃¢ 157
       while \exists p with free[p] = True and ready_p \neq \emptyset or
                                                                            deed achieve this, hence avoiding a communication. As such, this 154

  end while 10
  Note that both BSPg and Source only define the computation 5
phases of our schedule by assigning nodes to processors and super- 5
steps: the corresponding communication steps for each communica 5
tion phase are derived in the end according to a lazy communication 5
schedule
  The ILPinit initializer is discussed later, together with the re- 20
maining ILP-based methods. 10
A.3 Local search 5
Our hill climbing methods take an initial solution (BSP schedule)
provided by one of the initialization methods, and execute small 5
modifications to this schedule that decrease its total cost, until a 5
local minimum is reached where none of the modifications lead to 5
an improvement (or a predefined time limit is exceeded) 5
```

As mentioned before, from each current solution, we consider 11

the modification steps which only change the assignment of single 11

```
node v. In particular, if we currently have \pi(v) = p and \tau(v) = s.
we consider all the solutions for where we have \pi(v) \in \{1, ..., P\}
(i.e. v on any processor) and \tau(v) \in \{(s-1), s, (s+1)\} (i.e. v in the
previous, same, or next superstep), with the assignments for every 19
other node unchanged 19
  Our HC method also employs several data structures to ensure 5
that the cost of a potential modification can be computed efficiently 5
and the same data structures can also be updated efficiently after 5
executing a modification. For instance, for each superstep s, we 5
keep the work cost and the communication cost of each processor 5
in a sorted set, and for each processor p we keep an external pointer 5
to the entry describing this processor in the set; this allows for a 5
lookup of the maximum in O(1) time, and when updating the cost, 5
a deletion in amortized O(1) and an insertion in logarithmic time. 5
  Furthermore, for each node v and processor \underline{v}, we explicitly store 5
the first superstep s when node v is required on processor v (due 5
to one of v's direct successors): due to the lazy communication 5
schedule, this implies that v will be sent from \pi(v) to p in superstep 5
(s-1) (unless p=\pi(v)). This ensures that whenever we consider
moving v to a different processor, we can immediately identify 5
the communication steps that are affected by this change, and 5
hence we can efficiently compute the resulting change in the total 5
communication cost. 5
  The list of valid moves in the search space (i.e. modification 9
options that still provide a valid BSP schedule) is also computed in 9
a preprocessing phase, and maintained throughout the algorithm: 9
when a node v is moved to another processor and/or supersten, we 9
only need to update the possible move options for v and its direct 9
predecessors/successors.
  Together, these data structures ensure that in each step of HC, 10
we simply iterate through the list of valid move options, efficiently 10
check if any of them leads to an improvement, and apply the selected 10
move option, also updating our data structures efficiently
  The communication schedule hill climbing (HCcs) follows a very 11
similar approach. Note that this settings already considers the as-
signments \pi and \tau to be fixed. For each necessary communication 11
step (when v needs to be sent from \pi(v) to p), this assignment natu-11
rally defines an earliest and latest communication phase when this 11
transfer can happen: the earliest is \tau(v), and the latest is (s_0-1) for 11
the first superstep s_0 that assigns a direct successor of v to processor 11
p. Our HCcs method considers alternative communication sched- 11
ules with (v, \pi(v), p, s) \in \Gamma for different possible s \in [\tau(v), s_0 - 1]
As before, in each step, we consider a modification of selecting a 11
different such s for only one of the required communication steps. 11
with the remaining communication steps in Γ unchanged. Note that 11
for simplicity, this setting implicitly assumes that the value of v is 11
directly sent to p from the processor \pi(v) where it was computed. 11
Similarly to HC, this hill climbing also uses sorted sets and external 11
pointers to efficiently maintain the send cost and receive cost of 11
each processor in every superstep. 11
   For both hill climbing methods, there are two possible variants
we either (i) always greedily apply the first modification step that 23
we find which decreases the cost, or (ii) we always consider all the 23
possible modifications from the current solution, and select the one 23
which decreases the cost by the largest amount. Our preliminary 23
```

experiments have shown that neither of these two approaches is 23

clearly superior to the other in terms of the final schedule found, 173 however, the second method is much more time-consuming, since there are usually numerous possible modification opportunities to analyze from a given solution. Due to this, we have applied the former, greedy variant of the approach in our experiments. 173

In our experiments, we allow the HC+HCcs methods to run for a 174 time limit of 5 minutes on our main datasets, and for 30 minutes on 174 the huge dataset. Given such a time limit, we always allocate 90% of the allowed time to HC, and the remaining 10% to HCcs. 174

A.4 ILP-based methods

Our most sophisticated approach is the ILP-based solving of the 176 scheduling task or some of its subproblems 176

The general approach to formulate the scheduling problem as 177 an ILP has already been outlined in [28]: our model here corre- 177 sponds to the submodel called FS by the authors of [28]. In this full 177 ILP representation, there is a binary variable COMP_{v.p.s} to indicate 177 whether node v is computed on processor p in superstep s, and a 177 value PRES_{v.p.s} to indicate if the value of v is already available on p by the end of (the computational phase of) superstep s. Besides these, the communication steps are represented by binary variables 177 COMM_{v,p_1,p_2,s}, indicating whether $(v,p_1,p_2,s) \in \Gamma$. These variables 177 allow a natural way to express both the validity conditions of BSP model (precedence constraints and valid communication steps) and 177 the elements of the cost functions with auxiliary variables; see [28] 177 for details. For our ILPfull method, we implement the representa 177 tion above, with only minimal changes: we aggregate some of the 177 (originally separate) linear constraints into a single constraint, and 177 we replace the role of the explicit variables PRES_{v,p,s} by the unused 177 variables сомм_{v.р.р.s}. 177

In our ILPcs method to optimize the communication schedule, the main idea is similar to that of HCcs: we consider π and τ already fixed from the initial solution, and only try to optimize the necessary communication steps in Γ . Once again, the assignment defines an earliest superstep $\tau(v)$ and a latest superstep $(s_0 - 1)$ when we can send a value v from $\pi(v)$ to p if this is required. Hence for each $s \in [\tau(v), s_0 - 1]$, we define a binary variable $COMM_{v,p,s}$ to indicate whether the value is communicated in superstep s. Note that similarly to HCcs, this implicitly assumes that the value of v is always sent from $\pi(v)$. Given these variables, the main techniques in the ILPcs formulation are identical to ILPfull: we can use the same approach to ensure with linear constraints that the communication 178 costs are measured properly and that each communications step is indeed scheduled to some superstep.

The ILPpart and ILPinit formulations are similar to each other in the sense that they both only consider a particular subproblem (a 179 concrete subset of nodes V_0 and a concrete interval of supersteps S_0), and express this as an ILP. In ILPpart, we begin from a given subset of supersteps S_0 : we split the BSP supersteps into disjoint intervals (from back to front), and consider the nodes that are currently assigned to the supersteps in S_0 in order to obtain our V_0 . We form these intervals iteratively, always growing the current interval until $V_0 | \cdot |S_0| \cdot P^2$ exceeds 4000: this is because the number of variables in the ILP representation is in the magnitude of $|V_0| \cdot |S_0| \cdot P^2$, so we use this metric to estimate (and limit) the size of the ILP problem obtained. In contrast to this, in case of Il Pinit, we begin with a topological ordering of the DAG, and always select the next

batch of nodes in this ordering as V₀, and set S₀ to cover the next
supersteps: once again, the number of nodes in each batch is increased until |V₀| · 3 · P² exceeds a given threshold (2000 in this case).
179
Note that given V₀ and S₀, the ILP formulation for ILPpart

and ILPinit are similar, but differ in the fact that in ILPpart, all the nodes outside of V_0 are already assigned to a processor and superstep, whereas in ILPinit, the successors of the nodes in V_0 are not assigned yet (hence we disregard them for the optimization) 180

For the ILP formulation of ILPpart and ILPinit, it is not surprising that the variables $COMP_{v,p,s}$ and $COMM_{v,p_1,p_2,s}$ are restricted to $v \in V_0$ and $s \in S_0$. This already ensures that the ILP problem is drastically smaller than ILPfull, since the number of variables only scales with $|V_0|$ and $|S_0|$, instead of n and the total number of supersteps. However, in these ILPs, there are several further design decisions that allow us to reduce the number of required variables. 181 at the cost of some simple restrictions to the solution space. 181

• Some of the nodes $v \in V_0$ might have direct successors u 182 that are scheduled into supersteps after the interval S_0 . Let $\pi(u) = p_1$. Then e.g. if we originally had $\pi(v) = p_1$, but the ILP solver sets $\pi(v) = p_2$, then this results in a newly 182 required communication step; on the other hand, if we orig- 182 inally had $\pi(v) = p_2$, but the ILP solver sets $\pi(v) = p_1$, then 182 <u>a previous communication step becomes unnecessary. Note</u> 182 that these communication steps might either be within the 182 superstep interval S_0 , or after S_0 . In order to ensure that our superstep formulation only scales with $|S_0|$ (instead of also optimizing communications in supersteps after S_0), we choose to ignore the case when v was originally com- 182 municated after S_0 : in this case, reassigning v might make 182 this communication step unnecessary and hence reduce 182 the cost of an h-relation after S_0 , but we ignore this poten- 182 tial further gain in the ILP objective. On the other hand 182 whenever v is sent within S_0 , this is easily captured by our 182 formulation via the variables сомм_{и.р.р. s}. In particular, in 182 the last communication phase of S_0 , we only include the 182 variables $COMM_{v,p,p',s}$ for processors p' that require the 182 value of v after S_0 , but for these processors, we also add 182 the constraint that v indeed needs to be present on proces- 182sor p' by the end of S_0 . This ensures that our ILP indeed captures the fact that the reassignment comes with newly 182 required communication steps: however, it limits our flex- 182 ibility by requiring that these new communication steps 182 need to happen until the end of S_0 . 182

Some of the nodes $v \in V_0$ might also have direct predecessors u which are scheduled into supersteps before S_0 . 182 Similarly to the case of successors, if v is rescheduled to a different processor, then this might result in newly required communication steps or previous communication steps 182 becoming unnecessary. As before, the ignore the potential gains from removable communication steps that were scheduled before S_0 , in order to ensure that our ILP size only scales with $|S_0|$. Within S_0 , these communication steps 182 can once again be captured with variables $COMM_{u,D_1,D_2,s}$ 182 as before; however, we also need to add such variables for

the communication phase of the last superstep before S_0 . 5 Furthermore, note that the number of such predecessors 5 u can potentially be even larger than $|V_0|$, hence if we add these variables without consideration, they could notably 5 increase the size of the ILP. To avoid this problem in prac- 5 tice, we apply two simplifications. On the one hand, note 5 that Γ might ensure that the value of predecessor u is already communicated to several processors p_0 before S_0 ; 5 since u is always present on these processors throughout 5 S_0 , we do not the add the variables COMM_{u,p_1,p_0,s} in this 5 case, and we also disregard the precedence constraint (u, v) 5 for COMP_{v,p₀,s} (since they are satisfied anyway). On the 5 other hand, as before, we assume that the value of u is directly sent from $\pi(u)$ (which is fixed, since u is computed 5 before S_0) to any processor; this removes a factor P from 5 the number of communication variables for u. Finally, note 5 that there may also be predecessors u that have both an 5 out-neighbor $v \in V_0$ and an out-neighbor u' scheduled after 5 S_0 ; in this case, if u is originally sent to $\pi(u')$ during S_0 , 5 then we also need to add the constraint that the value of u 5 must still be present on $\pi(u')$ by the end of S_0 in our ILP 5 solution

 In our communication schedule Γ, we may also have communication steps (v, p_1, p_2, s) where v was computed before S_0 , it is only required on p_2 after S_0 , but our Γ still just happens to schedule it during the interval S_0 , even though v has no direct successor in V_0 . These communication steps have 9 no direct connection to the assignment of the nodes V_0 , but 9 they still contribute to the communication costs in one of the supersteps of S_0 . The number of these communication 9 steps can theoretically be as high as $\Theta(n)$; hence if we include them as optimizable options in our ILP formulation. 9 then we may lose the advantage of only scaling with $|V_0|$. 9 As such, we consider these communication steps fixed: the 9 communication costs they incur appear as a pre-computed 9 constant in the send and receive costs of the appropriate 9 processors in the given supersteps, unaffected by our choice 9 of the assignment for V_0 . 9

As mentioned before, we use the CBC open-source solver [7] for solving the ILP problems described above. Since ILPfull tries to solve the entire problem, we allow a larger time limit of 1 hour when running this method. ILPcs also looks for a global solution but in a much more restricted problem, so we set its time limit to 5 minutes, similarly to HC+HCcs. We select an even shorter time limit for ILPpart and ILPinit: 3 minutes for the former, 2 minutes for the latter (since this is supposed to be an even faster heuristic 13 just for initialization). Even this way, ILPpart and ILPinit still 13 dominate the running time of the algorithms in our experiments since both of these are iterative methods that are repeatedly applied on many different parts of the DAG or the schedule 13

A.5 Multilevel approach 12

Our most novel algorithmic contribution is perhaps the application 12 of the multilevel coarsen-solve-refine technique, which is a state-of-the-art approach in hypergraph partitioning tools [15, 31, 33, 37], to the domain of scheduling problems. We develop and analyze a 12

simple variant of this multilevel scheduling approach for the case	5
when a scheduling problem is dominated by very high communica-	
tion costs, since our other methods often fail to find high-quality	5
solutions in this case. 5	
In the first phase of the multilevel algorithm our goal is to grad-	13
ually coarsen the DAG into a significantly smaller representation	
that captures most of the structure of the original DAG. For this.	13
we repeatedly contract a directed edge of the DAG into a single	13
node_combining all the incoming and outgoing edges of the two	13
nodes. Each such operation reduces the number of nodes by exactl $oldsymbol{ au}$	13
one, so a repeated execution of this procedure allows us to obtain a	13
coarsified DAG representation of any desired size. 13	
In order to have a valid schedule that can be interpreted for	24
each intermediate step of the coarsening procedure, it is critical to	24
ensure that our graph indeed remains a DAG after each contraction	24
step. We ensure this by only selecting edges to contract in each	24
step that satisfy this property. In particular, an edge $(u,v) \in E$ can	
<u>be contracted into a single node (without creating a directed cycle)</u>	
if and only if there is no other directed path in the DAG from u to $oldsymbol{\imath}$	
apart from the edge (u, v) . Note that there are always contractable	
edges in a DAG: e.g. each non-sink node u can be contracted with	
its out-neighbor v that appears earliest in a topological ordering.	24
since there can be no other directed path from u to v 24	
In our algorithm, we evaluate the contractable edges (u, v) based	
on two properties: (i) the total work weight $w(u) + w(v)$ that we	
would obtain after contraction, which should be small to ensure	
that no large cluster of nodes is forced onto the same processor	
in the same superstep, and (ii) the communication weight $c(u)$	
of the source node, which should preferably be large, since the	
contraction step implies that the output of u will not require a	
communication step to be sent to $\pi(v)$, at least not due to this	
edge. In our implementation, we consider the following simple	
technique: we sort the list of contractable edges in an increasing	
order according to $w(u) + w(v)$, and we always select from the first	
a of this list to ensure that we do not merge nodes with large work	24
weight. From this first part of the list, we select the edge with the	15
largest $c(u)$ value Note that after the contraction step, we sum up both the world	24
weights and the communication weights of u and v to obtain the	
weights for the contracted node. This is entirely appropriate for	
work weights, since these are summed up on the same processor	
and superstep anyway. For communication weights, this only gives	
us an estimate (upper bound) on the actual communication require-	
ments: if there is an edge (u, v) in our coarsened DAG, then from	
(possibly many) original nodes contracted into u , maybe only a few	24
had an actual edge to v . This means that when a scheduling of the	24
coarse DAG sends the value of u to v , and computes the cost of this	
based on summed weights $c(u)$, then this is only an upper bound	
on the amount of data that actually has to be communicated. 24	
In our implementation of this coarsening phase, we find the list of	24
all contractable edges in the DAG in the beginning, and we update	
this list after each contraction step. Note that after contracting	
(u,v), this does not only involve updating the edges incident to u	
and v: there might be edges arbitrarily far in the DAG that become	
uncontractable after this step. In particular, if there is another edge	

(u', v') such that there is a long directed path from u to v', and

another one from u' to v, then both edges are contractable originally. 190 however, after contracting (u, v), there will be a directed path from u' to v' via the contracted node, so this distant edge (u', v') loses 190 its contractability. 190

In general, we note that in our implementation, each of the contraction steps are rather time-consuming, due to e.g. the need to update the edges described above, and because we always iterate through the list contractable edges to select the one with highest c(u); both of these operations can require O(|E|) time for each contraction step. This is not a problem in our work, since our more complex scheduling methods require significantly more running time anyway. However, it is an interesting question for future work whether we can develop efficient coarsening techniques with significantly smaller time complexity 191

Another crucial question regarding the coarsening phase is the 192 optimal amount of coarsening that provides the best schedule in 192 the end. A too coarse DAG might not capture the overall structure 192 well enough, whereas an insufficient amount of coarsening might 192 not provide the advantages of the multilevel approach; in particular, 192 in our setting it might not remedy the problem of excessively 192 high communication costs (i.e. that it is only beneficial to reassign 192 larger clusters of nodes simultaneously). This task of finding the 192 most favorable coarsening ratio is a very challenging and complex 192 problem on its own; investigating this in detail is far beyond the 192 scope of our paper. For our preliminary experiments to validate the 192 multilevel approach, we simply select two specific rates: we coarsen 192 the DAG to 30% and 15% of its original size, run the multilevel 192 approach for both of these cases, and out of the two schedules 192 obtained this way, we select the one with lower cost as the final 192 output of our multilevel scheduler, 192

We also note that our main question in this coarsening phase was to obtain a significantly coarsened version of the DAG that 193 maintains the acyclic property. This general question has been 193 studied by multiple works in recent years [10, 31], but was mostly evaluated as a partitioning problem in itself, rather than analyzed as a tool for scheduling. The work of [27], as mentioned before, is an exception to this, which has applied one of these acyclic partitioners 193 to further improve state-of-the-art list schedulers. However, in 193 contrast to our iterative coarsening procedure, this approach applies 193 a final acyclic partitioning: as such, it offers no straightforward way 193 to uncoarsen the DAG gradually, and hence there is no opportunity 193 to execute further refinement steps in a multilevel fashion in this 193 case 193

The solving phase is the simplest part of the multilevel approach:

here we apply the algorithmic pipeline of Figure 3 on the coarsened DAG. In particular, recall that ILPfull is only applicable on
very small DAGs, and ILPpart is also significantly more useful on
smaller DAGs; as such the multilevel approach allows us to also
apply these methods more successfully on DAGs that are originally
larger 194

In the uncoarsening and refinement phase, we gradually undo
the contraction steps in a reverse order, thus moving closer and
closer to our original DAG. Every time after we execute a given
number of uncontraction steps, we refine the current schedule. That
is, we first project our current schedule (obtained from the solving
phase or the previous refinement step) into our current, slightly
195

more uncoarsened DAG: we assign each node to the same processor	
and same superstep as its contracted counterpart. Note that since	
	195
	195
	195
	195
several improvement steps with our local search method (HC) to	195
obtain a slightly more refined variant of our current schedule on 1	195
this slightly more coarsified version of the DAG 195	
In our experiments, we choose to refine the schedule after every	196
5 uncontraction steps, and we run HC for at most 100 steps (or until 1	196
a local minimum is reached). This makes the number of refinement 1	196
phases proportional to the number of contraction steps: alterna-	196
tively, one could also opt to only have a fixed number of refinement 1	96
phases altogether 196	
We also note that this uncoarsening phase (and hence the whole	97
multilevel approach) can be adapted much more naturally to BSP 1	97
than to classical models: if nodes are assinged to concrete starting	97
times instead of supersteps, then it is not immediately clear how	197
a schedule on a coarser DAG should be projected to a slightly 1	197
uncoarsened variant of the same DAG 197	
Recall that during the refinement steps, we only apply HC, but	98
not HCcs, since the (partially) coarsened DAG often overestimates 1	98
the required amount of communications (as it merges the weights 1	98
$c(v)$ in each cluster). Instead, HCcs and ILPcs are applied separately $ec{}$	198
on the original DAG after the uncoarsening has been finished. 198	1
Regarding the entire multilevel approach, we note that our im-	199
plementation is only a preliminary exploration of this idea, and	199
each element of this approach can be further improved to obtain a	199
more advanced version of this algorithm. In particular, analyzing 1	199
more complex DAG contraction methods, or refinement with more	99
advanced algorithms, or clever methods to estimate the optimal 1	
coarsification factor are all promising directions for further im-	199
provement. We leave it to future work to investigate these more	99
sophisticated variants of the approach 199	
Finally, as a side note, we point at that the work of [27] also 2	200

Finally, as a side note, we point at that the work of [27] also applies the concept of Communication-to-Computation Ratio (CCR) to capture the concept that a scheduling problem is dominated by communication costs, i.e. when our multilevel algorithm seems superior to other methods. In the work of [27], CCR was simply defined as the ratio of $\sum_{v \in V} c(v)$ and $\sum_{v \in V} w(v)$. This metric is not straightforward to generalize to our model with significantly more parameters: multiplying the numerator with g and also the average NUMA coefficient $\frac{\sum \lambda_{p_1,p_2}}{p^2}$ is a rather natural extension, but it is not trivial to include e.g. the effect of the parameter ℓ in this formula 200

B DETAILS ON THE DAG DATABASE 201

This section discusses the details on our computational DAG database. We note that the database itself (coarse grained instances, fine-grained generator, some examples files and tools) are available at https://github.com/Algebraic-Programming/HyperDAG_DB. The test set of DAGs used in our experiments are available with the remaining supplementary material in [1] 202

As noted before the DAGs in our database are stored in a hyperDAG format, to be in line with the recent works of [29, 31] 203

However, this difference is only relevant from a theoretical modelling perspective, to emphasize the fact that even if a node v has multiple out-neighbors on another processor p, its output only needs to be sent to p once; due to this, for partitioning problems, it is more adequate to represent the output data of v as a hyperedge containing v and all its out-neighbors. For our work, this is simply an alternative representation of the precedence constraints in the DAG, and hence it has no effect. In fact, all of our algorithms begin with the simple step of transforming these hyperDAGs back into a regular DAG representation.

B.1 Coarse-grained DAGs

In order to obtain the coarse-grained representation of a variety of computations, we considered the GraphBLAS implementation of 45], and extended this with a so-called HyperDAG backend. The goal of this backend is to run simultaneously to a regular Graph-BLAS algorithm and gather meta-data during this run, which is then used to generate the representation of the executed computation.

For this, the backend considers the various operation primitives that are used as building blocks for the computations in Graph-BLAS, and ensures that each of these primitives identifies the inputs and outputs of the given operation, allowing us to reconstruct the structure of the computational DAG.

This backend automatically allows us to extract the DAG representation of a wide variety of algebraic computations implemented in GraphBLAS. This involves common iterative methods for linear solvers (e.g. Conjugate Gradient for positive definite systems, or BiCGStab for general systems). graph algorithms that are naturally expressible in an algebraic form (such as *k*-hop reachability connected components, or the PageRank algorithm), classical or more advanced methods from machine learning (such as *k*-means, label propagation or sparse neural network inference), and more. For more details on the concrete GraphBLAS computations, we refer the reader to [45]. We note that several of the algorithms above are iterative methods; for these, we extract the corresponding computational DAGs both for a predefined small number of iterations (we set this to 3) and for the case when the algorithm is running until the iterative method converges.

We note that while larger containers (matrices, vectors) are easy to track within a GraphBLAS algorithm, some simpler data structures, such as scalars, are not trivial to track without introducing textensive changes to the algorithm implementations. Due to this our extraction from GraphBLAS sometimes provides an incomplete DAG representation, leading to some isolated nodes or smaller isolated components in the resulting DAG. To obtain the test DAGs for our experiments, we simply consider the largest connected component in each of the extracted DAGs; while this does not always cover the entire GraphBLAS algorithm in question, it still represents a subDAG that corresponds to a valid (sub)computation, and anyway captures most of the structure of the whole computation in the majority of cases 5

Note that assigning work weights w(v) and communication weights c(v) to the nodes of the extracted DAG is a non-trivial 24 task: while the DAG structure of the computation is fixed for an algorithm, the sizes of the matrices and vectors involved can be arbitrary, based on the inputs in the concrete run. As such, for simplicity, we assign w(v) = indeg(v) - 1 to each node v of the 24

DAG, where indeg(v) is the indegree of v: since the operation v represents combining indeg(v) distinct values, indeg(v) – 1 is a reasonable estimation for the workload this requires (consider e.g. 5 a summation or a multiplication). The only exception to this is 5 the source nodes of the DAG, where instead of setting w(v) = 0, we still assign a work cost of w(v) = 1: while they correspond to inputs of the computation, loading or initializing these values might 5 still require some computational resources. As for communication 5 weights, we uniformly assign a weight of c(v) = 1 to all nodes in 5 the coarse-grained DAG. We leave it to potential future work to 6 develop a way to assign more accurate weights to the nodes in 5 these extracted DAGs. 5

B.2 Fine-grained DAGs 13

10	
In order to obtain fine-grained DAG representation of algebraic	13
computations, we have implemented a simple generator tool that	13
synthetically creates and outputs the computational DAG corre-	13
sponding to a few specific algebraic computations. Each of the four	13
computations depend on a square matrix A. In our experiments.	13
A is always defined by a size N (number of rows/columns). and	13
a probability parameter a such that each entry in the matrix is	13
nonzero independently with probability a. To construct computa-	13
tions from real-world matrices, the generator also has the option	13
to load input matrices (i.e. nonzero patterns) from a file, but this is	13
not used in our experiments. 13	

Given this input matrix, our tool artificially creates the fine-5 grained computational DAG corresponding to this matrix, with each 5 node describing a simple operation with a few nonzero values (e.g. 5 addition or multiplication of scalars). In particular, the generator 5 outputs DAGs corresponding to the following algorithms:

- spmv: multiplication of a sparse matrix *A* with a dense vector *u*. An example for this operation is also shown in Figure 5 2.5
- exp: an iterative version of spmv, i.e. given a sparse matrix
 A with a dense vector u, the naive computation of the vector
 A^k·u, by executing k distinct spmv operations. This computation is an important building block of many applications
- CG: the well-known conjugate gradient method for finding a numerical solution to a system of linear equations, executed for k iterations.
- kNN: in GraphBLAS, this method refers to finding the nodes in a graph that are at most k hops away from a specific node (in contrast to machine learning, where k-NN usually covers a different concept). In terms of algebraic computations, this can be represented as to the multiplication of sparse 12 matrix A and a vector u with a single non-zero entry for k 12 iterations.

Besides N and q another defining parameter for the last three 13 algorithms is the number of iterations k 13

As before, the work weight is set to 1 for source nodes, and to 24 the indegree of the node minus 1 for all other nodes; this is indeed 24 realistic for our fine-grained DAGs, since e.g. the addition of 4 24 scalars indeed requires 3 addition operations. The communication 24 weights c(v) are again set to 1 for all nodes. 24

B.3 Datasets for our experiments 215

To form our datasets, we generate fine-grained DAGs for different 216 n values, and we also strive to produce DAGs of different shape: e.g. 216 a higher number of iterations k results in a deeper DAG (where the 216 longest path is longer), in contrast to a smaller k, or in contrast to 216spmv DAGs where no iterations happen at all, and the longest path 216 always has size only 3. 216

For the dataset used for the initial training, we create 10 fine- 217 grained instances, with n ranging from 15 to 1950, 217

For the actual test datasets, we always specified an interval 218 for *n* first ([40,80] for tiny, [250,500] for small, [1000,2000] for 218 medium and [5000, 10000] for large), and we specifically created 218 a fine-grained DAG with each of the 4 methods in our generator 218 that is approximately in the beginning, middle, and end of this 218 interval. This results in 12 fine-grained DAGs for the tiny set. For 218 the remaining sets, there is a higher number of possible parameter 218 combinations to create DAGs in the interval; as such, with all the 218 iterative methods that allow more freedom to influence the depth 218 of the DAG (i.e. exp, cg and kNN), we create two different DAGs, a 218 deeper and a wider one, for the beginning, middle, and end of each 218 node interval. This results in 6 fine-grained DAGs with exp, cg and 218 kNN, and 3 fine-grained DAGs with spmv. Hence altogether, we have 218 21 fine-grained DAGs in the small, medium and large datasets. 218

Besides this, we also add to each dataset the coarse-grained 219 instances in our database where the number of nodes fits into the 219 defined interval. This adds 4 coarse-grained DAGs to the tiny 219 dataset, and 3 coarse-grained DAGs to the small dataset. 219

In order to create the huge dataset, we generate 7 fine-grained 220 instances with $n \in [50000, 100000]$: one with spmv, and two with 220

each of the remaining algorithms. We then extend this with 3 coarse-220 grained instances where n is in a similar magnitude (one of the 220 instances only has n = 47023, the other two are within the interval). 220

We begin by discussing our preliminary runs on the training set 223 to evaluate the performance of the different initialization methods. 223

DETAILS ON THE EXPERIMENTS 221

C.1 Comparison of initializers 222

With the 10 training set DAGs and 9 parameter combinations from 223 $P \in \{4, 8, 16\}$ and $q \in \{1, 3, 5\}$, this amounts to 90 runs altogether. 223 During these runs, we found that each of our initialization methods can outperform the others. In particular, the best schedule 224 was returned by BSPg in 44 cases, by Source in 20 cases and by 224 ILPinit in 26 cases. Furthermore, we can observe that the relative 224 performance of the heuristics show a strong dependence on the 224 properties of the scheduling problem itself; in particular, on the 224 size of the DAG, the number of processors P, and besides these. 224 also on the "shape" of the DAG: the shallow DAGs produced by 224 spmv computations behave rather differently from the rest of the 224 fine-grained DAGs. 224

In particular, Tables 4 and 5 show the number of times each 226 heuristic turned out to be the most successful. Table 4 for spmv 226 computations, and Table 5 for all other fine-grained instances com- 226 bined. Table 4 is separated according to P. while Table 5 is separated 226 according to P and n. There are several straightforward observa- 226 tions from these tables. On the one hand, it is clear that Source is 226 rather effective for the shallow spmv DAGs, but not very useful 226 otherwise. ILPinit performs well either for very small DAGs, or 226 for very small P. Finally, BSPg consistently delivers good results for 226 most of the parameter combinations 226

Since ILPinit is a very time-consuming initialization methods, 228 based on these observations, we decide to only run ILPinit for 228 problems with P = 4 processors in the experiments; this significantly 228 reduces the running time required for the experiments. Although 228 ILPinit is also often superior when n is small, we do not apply it 228 in this case, since ILPfull and ILPiter can essentially fulfill the 228 same role for these problems. Since both BSPg and Source are very 228 fast heuristics with negligible running time compared to the other 228 elements in our framework, we apply both of them on every input 228 problem_regardless of the parameters 228

C.2 Experiments without NUMA 230

The results of our experiments without NUMA effects have alread 230 been outlined in Section 7. For completeness, here we provide a 230 table with the respective improvements for each combination of 230 P. a and dataset, shown in Table 6. Note that each number in the 230 tiny, small, medium and large rows is still the average of 16, 24, 230 21 and 21 runs on different DAGs, respectively. This more detailed 230 table reveals some further details compared to Table 1; for instance. 230 while the cost reduction generally increases with larger P, this in 230 fact only holds for the larger datasets, and the effect is in fact the 230 opposite for the tiny DAGs. It also shows that for the most extreme 230 subcase, our scheduler achieves almost a factor 2× improvement 230 with respect to HDagg, and well over a factor 2× improvement with 230 respect to Cilk, even in this non-NUMA setting. 230

Table 6: Improvement achieved by our scheduler (without NUMA) for each combination of q, P and dataset, with respect to Cilk (first number in cell) and HDagg (second number in cell). 12

	q = 1 33			q = 3 45			q = 5 33

small	1.54	1.073	1	0.791	0.66	0.579	0.556	0.539
medium	1.896	1.254	1	0.658	0.592	0.542	0.529	0.506
large	2.142	1.517	1	0.609	0.591	0.547	0.542	0.521

Table 8: Cost reduction achieved by our scheduler compared 5 to ETF on the tiny dataset, for each combination of g and P, 5 without NUMA. 5

	g = 1	<i>g</i> = 3	g=5	33
P=4	38%	43%	46% 3	3
P = 8	33%	31%	32%	
P = 16	22%	27%	28%	

Table 9: Cost reduction achieved by our scheduler for dif- 5 ferent values of ℓ , on the medium dataset for g = 1 and P = 8 5 (compared to Cilk/HDagg). 5

$\ell = 2$	$\ell = 2$ $\ell = 5$		$\ell = 20$	
38% / 16%	43% / 17%	50% / 19%	58% / 21%	

In order to better understand the different ILP methods we show the performance of each algorithm on the datasets for q = 5 (and all of $P \in \{4, 8, 16\}$) in Table 7, with the ratios normalized to Cilk as in our figures before. The ILPpart column shows the relative cost of the schedule after running ILPfull and ILPpart, whereas ILPcs shows the final schedule after also running ILPcs. The table shows that in the tiny dataset, ILPfull/ILPpart has a significant effect decreasing the mean ratio from 0.619 to 0.569, which amounts to a 5% cost decrease from 0.619. As n grows larger, the improvement of

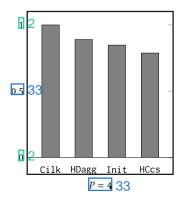

achieved by these methods becomes less significant. In contrast to this, ILPcs only achieves a minimal improvement on the smaller dataset, but it is more impressive when *n* is larger: it decreases the ratio from 0.529 to 0.506 on medium and from 0.542 to 0.521 on large (4% improvement in both cases). This suggests that ILPpart and ILPcs excel in different situations, and hence they are both valuable ingredients in our scheduler.

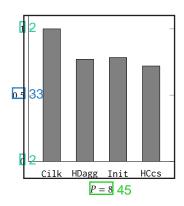

The table also contains our other academic baselines, ETF and BL-EST. The data shows that as *n* grows, even Cilk becomes more superior to both ETF and BL-EST. Also, both ETF and BL-EST are significantly outperformed by HDagg, except for a single case: ETF performs better than HDagg on the tiny dataset. Since ETF is the strongest baseline altogether for this specific dataset, for completeness, we also show the cost improvement of our scheduler on the tiny dataset compared to ETF in Table 8. The table shows that our scheduler is also consistently superior to ETF by a significant margin.

C.3 The role of latency 5

So far, we always had a fixed choice of $\ell = 5$ in our scheduling problems. As such, we also run a small experiment to investigate the effect of the parameter ℓ on our schedules. For this, we consider the medium dataset, with a choice of q = 1 (to ensure that communication costs are dominated by ℓ) and P = 8. We investigate different values for the latency in this setting: $\ell \in \{2, 5, 10, 20\}$.

We show the improvement achieved by our scheduler for each of these cases in Table 9. The table shows that similarly to <u>a</u>, the improvement increases for larger values of ℓ . However, in contrast to <u>a</u>, the latency needs to be set to much larger numerical values in order for this tendency to become clearly noticeable.

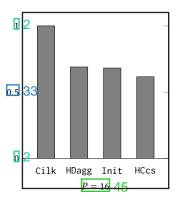

Figure 7: Improvement achieved by the initialization methods and the local search algorithm on the huge dataset, separated 10 according to the value of P. 10

C.4 Experiments with NUMA

In our experiments with NUMA effects, we only considered P=8 and P=16 for the number of processors, since even as a binary 12 tree, P=4 gives a very shallow hierarchy with only two levels Similarly, we only considered g=1, since with P=16 and $\Delta=4$ this already gives a coefficient as high as $\Delta^3=64$ between pairs of processors that are only connected over the highest level of the hierarchy. As before, we set $\ell=5$. For the NUMA multiplier, we consider the values $\Delta \in \{2,3,4\}$. Generally, as n grows larger, the improvement with respect to HDagg typically get smaller, whereas the improvement with respect to Cilk does not show such a clear pattern in terms of n 12

The improvements achieved by our scheduler, separated according to *P*, Δ and the dataset, are shown in Table 10. The table confirms that the improvement achieved by our scheduler grows with a larger *P* and Δ and this general rule holds consistently for all cases in all of the datasets, i.e. regardless of *n*. Compared to Cilk, the difference between the parameter combinations is most significant in the tiny dataset: the smallest and largest improvement is both achieved in this dataset.

Recall that the same results are aggregated over the different 12 dataset (for each *P* and Δ) in Table 2. Finally, combined over all 12 datasets and all values of *P* and Δ , the mean improvement is 60% and 43% compared to Cilk and HDagg, respectively. We note that 12 ETF and BL-EST are also clearly inferior in this setting with NUMA 12 effects: on all datasets combined, they returns a schedule that is on 12 average 4% and 41% worse, respectively, than even Cilk, 12

C.5 The huge dataset 13

Our results on the huge dataset without NUMA effects are shown in Table 11, for separate values of *P* and *a*. As mentioned before in Section 7, the improvement compared to Cilk ranges from 15% to 41%, and the improvement to HDagg ranges from 6% to 13%. 13

To also see the amount of improvement we can attribute to the initializers and to HC+HCcs, we illustrate the improvement in Figure 7. This shows that the initializers achieve a 15%, 22% and 32% cost reduction compared to Cilk (for *P* = 4, 8, 16, respectively). The local search methods then further improve this by 7%, 8% and 10% (for *P* = 4, 8, 16, respectively) compared to Init. Hence even for these much larger DAGs, without applying our ILP-based methods

our schedulers achieve a rather significant improvement to Cilk, 24 especially for higher *P* values. When compared to HDagg, we see 24 that Init is approximately on par with this baseline, and altogether 24 Init+HC+HCcs provides an improvement of 11%, 7% and 11% (for *P* = 4, 8, 16, respectively). We leave it to future work to improve the scaling of our algorithms, to ensure that they are also superior 24 to HDagg by a more significant margin for DAGs of this size. 24 The results on the huge dataset with NUMA effects are mostly similar; these are shown in Table 12, separated according to *P* and 13 A. The improvement here ranges from 30% to 48% compared to 13 Cilk, and 7% to 21% compared to HDagg. As such, similarly to the

smaller dataset, the improvements become larger when we have 13

NUMA effects: however, the difference between our scheduler and 13

HDagg still remains relatively small in several of the cases. 13

C.6 Multilevel scheduling 5

We primarily experiment with our multilevel scheduler in the settings where the communication costs are high; in our case, this mostly means the setting with NUMA effects. In our experiments, we only consider the multilevel scheduler on the small, medium and large datasets, since coarsening the DAGs in tiny would lead to an absurdly small DAG representation with as few as 6 nodes in the most extreme case. 5

Note that if the communication costs are very high in general 5 (such as with NUMA), then finding a good schedule becomes a 5 very challenging task: intuitively, it is only beneficial to assign two 5 parts of the DAG to separate processors if the relative size of these 5 parts is much larger than the number of edges going between them. 5 otherwise the corresponding communication steps result in more 5 extra cost than what we gain from the parallel execution of the 5 subtasks. In particular, when we have high NUMA costs in our 5 model, it can happen in our experiments that the best solution 5 found by both the baseline methods and our scheduler is in fact $5\,$ more costly than the trivial solution of assigning the entire DAG to 5 a single processor and single superstep. This clearly shows that the 5 schedulers (both the baselines and ours) fail to find any reasonable 5 schedule in this case. In particular, with very high communication 5 cost parameters, it is not even clear at first whether a solution 5 of lower cost even exists (just not found by our schedulers), or 5

Table 10: Improvement achieved by our scheduler (with NUMA) for each combination of P, Δ and dataset, with respect to Cilk (11 (first number) and HDagg (second number), for a fixed choice of q = 1 (and $\ell = 5$).

		$P = 8 \ 45$,	P = 16 45			
				$\Delta = 2$	$\Delta = 3$	$\Delta = 4$

P = 16	41% / 12%	45% / 16%	48% / 21%

whether the trivial solution mentioned above is in fact the optimal 8 schedule in these problems. 8

Our multilevel algorithm answers this question, demonstrating that an approach designed especially for this communication-heavy case can find a solution with lower than the trivial cost even in this very challenging setting. In particular, over all experiments with NUMA costs ($P \in \{8, 16\}, \Delta \in \{2, 3, 4\}$), there were as many as 114 out of 396 cases where our base scheduler (and the baselines) could not find a solution with lower than trivial cost; however, with the application of the multilevel algorithm, the number of such cases was only 8 out of 396. These numbers are understood over all datasets except tiny (where multilevel scheduling was not applied and hence it cannot be included in this comparison). This shows that even our relatively simple implementation of this multilevel diea can indeed very nicely fill the specialist role of scheduling these kind of problems.

The concrete improvement factors achieved by our multilevel algorithm (separately for $P \in \{8, 16\}$, $\Delta \in \{2, 3, 4\}$) are shown in Table 13 with respect to the baselines, and in Table 14 with respect to our (non-multilevel) scheduling framework. The tables show 5

that compared to the baselines, the multilevel approach can achieve a cost reduction of up to 87% and 79% in the most extreme case 5 (with respect to Cilk/HDagg), which is more than a factor 7.7× 5 improvement from Cilk and more than a factor 4.7× from HDagg. 5 When compared to our base scheduling framework, the multilevel approach clearly remains inferior when $\Delta = 2$, it is approximately equally strong when $\Delta = 2$ and P = 8, and is clearly superior when we have $\Delta = 3$ and P = 16, or $\Delta = 4$. For the most extreme case of $\Delta = 4$ and D = 16, it provides another more than D = 16, it provid

Note that the tables are split into multiple rows based on whether we use the approach with a coarsification factor of 0.15 or 0.3, or 5 whether we run both and select the better out of the two schedules 5 The table shows that applying and comparing both coarsifications 5 indeed leads to some further improvement over the single-ratio 5 approach. In case if we prefer running the multilevel approach with 5 only a single ratio 0.3 seems to be the clearly superior choice from 5 the two 5

In contrast to these cases, when we apply the multilevel scheduler to settings with lower communication costs, it typically provides weaker schedules than our base scheduling approach. This was already indicated before by the case of $\Delta=2$ in Table 14. In our setting without NUMA, the difference is even larger: for instance, the mean ratio of the multilevel algorithm to our base scheduler is 1.246 for a choice of P=8 and q=3, and 1.515 for a choice of P=16 and q=1 (still understood over all datasets except tiny). While these ratios imply that the multilevel approach is still somewhat better than Cilk (and even marginally better than HDagg in the P=8, P=8

However, we believe that with further polishing, the multilevel 5 approach can be improved to find a favorable coarsification ratio by itself (intuitively, to decide if coarsification is even necessary, or in a more advanced case, on which parts of the DAG it is necessary) 5 and hence it can become a technique that provides high-quality 5 schedules on all problems, regardless of input parameters. We believe that this is one of the most promising directions for future 5 work in this topic 5

Table 13: Cost reduction achieved by the multilevel scheduler in case of NUMA with respect to Cilk/HDagg, for each combination of P and P0, on the combination of all datasets except tiny, for a fixed choice of P1 (and P2). The rows P3 and P3 show the result obtained when running the multilevel algorithm with a coarsification factor of 15% and 30%, respectively, while the P4 coarsification factor of 15% and 30%, respectively, while the P5 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P6 coarsification factor of 15% and 10%, respectively, while the P7 coarsification factor of 15% and 10%, respectively, while the P8 coarsification factor of 15% and 10%, respectively, while the P7 coarsification factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% and 10% are also as a factor of 15% are also as a factor of 15% are also as a factor of 15% are also as a facto
