Abstract 126

Inverse graphics – the task of inverting an image into physical variables that, when rendered, 2 enable reproduction of the observed scene — is a fundamental challenge in computer vision 2 Disentangling an image into its constituent elements, such as the shape, 2 color, and material properties of the objects of the 3D scene that produced it, requires 2 a comprehensive understanding of the environment. This requirement limits the ability 2 of existing carefully engineered approaches to generalize across domains. Inspired by the 2 zero-shot ability of large language models (LLMs) to generalize to novel contexts, we in-2 vestigate the possibility of leveraging the broad world knowledge encoded in such models 2 in solving inverse-graphics problems. To this end, we propose the Inverse-Graphics Large 2 Language Model (IG-LLM), an inverse-graphics framework centered around an LLM, that 2 autoregressively decodes a visual embedding into a structured, compositional 3D-scene rep- 2 resentation. We incorporate a frozen pre-trained visual encoder and a continuous numeric 2 head to enable end-to-end training. Through our investigation, we demonstrate the poten-2 tial of LLMs to facilitate inverse graphics through next-token prediction, without the use 2 of image-space supervision. Our analysis opens up new possibilities for precise spatial rea- 2 soning about images that exploit the visual knowledge of LLMs. We will release our code 2 and data to ensure the reproducibility of our investigation and to facilitate future research 2 at https://ig-llm.is.tue.mpg.de/2

1 Introduction 3

The formulation of vision as "inverse graphics" traces its roots back at least to Baumgart (1974) (see also 4 Kersten & Yuille (1996) and Yuille & Kersten (2006)). While the term encompasses various ideas and 4 approaches to vision problems, it is often equated with "analysis by synthesis" (Grenander, 1976–1981). 4 What is typically meant here, however, is more akin to model fitting. This generally presupposes that one 4 has models of the world, knows roughly where they are, and then fits them to image evidence. 4

A more strict interpretation of inverse graphics targets the creation of a graphics program (Ritchie et al., 8 2023): a structured representation that can be used by a rendering engine to approximately reproduce the 8 3D scene. These programs are compact and interpretable representations of visual primitives (Wu et al., 8 2017; Jones et al., 2023), thereby aiding scene comprehension (Wu et al., 2017; Vi et al., 2018). The objective

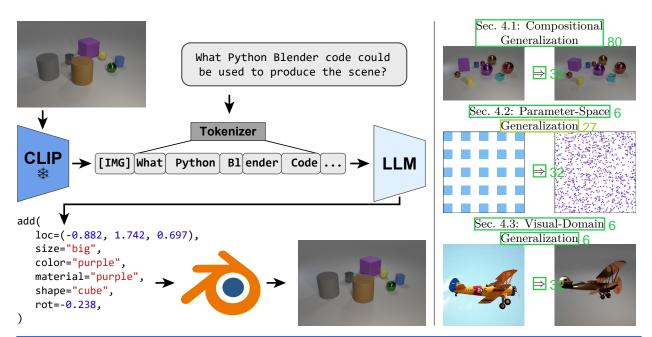

Figure 1: **IG-LLM.** We present the Inverse-Graphics Large Language Model (IG-LLM) framework, a general 7 approach to solving inverse-graphics problems. We instruction-tune an LLM to decode a visual (CLIP) 7 embedding into graphics code that can be used to reproduce the observed scene using a standard graphics 7 engine. Leveraging the broad reasoning abilities of LLMs, we demonstrate that our framework exhibits 7 natural generalization across a variety of distribution shifts without the use of special inductive biases. 7

extends beyond mere pixel- or object-level interpretation of an image; it seeks to leverage the inherent spatial 8 and physical relationships among objects that are essential for holistic scene understanding. 8

Our goal is to generate such a graphics program from a single image capable of reproducing the 3D scene and 9 its constituent objects using a traditional graphics engine. This approach, known as visual program induction, 9 has garnered significant attention, encompassing works on a variety of problem domains. Wu et al. (2017) 9 propose the concept of "neural scene de-rendering," wherein custom markup code, translatable into renderer-9 friendly inputs, is inferred from images. While their method handles synthetic scenes featuring arbitrarily 9 many objects, it grapples with generalization beyond its training-data distribution. Subsequent research (Yi 9 et al., 2018) explores the utility of graphics programs for the downstream task of visual question answering 9 (VQA). However, their scene-reconstruction method still struggles with generalization, particularly regarding 9 objects with unseen attribute combinations (e.g., a known shape with a novel shape-color combination). 9

To address the problem of generalization, a method must possess a deep understanding of the visual world and its physical properties. Here, we explore whether we can exploit the generalization abilities of large language models (LLMs) for this purpose. LLMs have demonstrated remarkable performance across a wide variety of vision—language tasks, ranging from producing detailed textual descriptions of images (Alayrac et al., 2022) and generating realistic images from text (Koh et al., 2023), to tasks such as visual question answering (Ouyang et al., 2022; OpenAI, 2023), visual instruction following (Liu et al., 2023; Zhu et al., 2023), and robot planning (Huang et al., 2022; Singh et al., 2023). Intriguingly, these models are designed with generic architectures and are initially trained with objectives that are not specifically tailored to a downstream task. The breadth of their training data endows them with the capacity for compositional to reasoning about the world. However, their proficiency in conducting precise spatial reasoning within the 3D Euclidean world remains largely unexplored. This prompts the question: Can LLMs, originally used to address semantic-level queries, be applied to the precise realm of inverse-graphics tasks? And if so, how?

To address these questions, we investigate the potential of LLMs to perform such tasks. We hypothesize that 11 LLMs can be trained with simple demonstrations to perform precise inverse-graphics reasoning. This idea 11 draws inspiration from instruction tuning (Taori et al., 2023; Chung et al., 2024) in the language-processing 11

domain, where LLMs acquire instruction-following skills after being fine-tuned on a limited set of curated 11 data. We anticipate that LLMs, endowed with broad knowledge about the physical world, can be taught 11 to recover accurate graphics programs from images beyond the training distribution. This insight motivates 11 a re-evaluation of the conventional inverse-graphics pipeline, leading to the proposal of a new LLM-based 11 framework: the Inverse-Graphics Large Language Model (IG-LLM). We fine-tune an LLM equipped with a 11 pretrained text-aligned vision encoder, using an instruction-based synthetic dataset, and explore the model's 11 capacity to infer graphics programs with accurate estimates of object quantity, shape, size, color, material, 11 location, and orientation, as illustrated in Fig. 1. 11 However, a question arises regarding the suitability of LLMs and natural language for generating the precise 12 measurements necessary for inverse graphics, given the discrete nature of their token-based output. This 12 constraint poses challenges for reasoning within metric spaces such as Euclidean space. To address this, we 12 explore the integration of a *numeric head* in the language-based output (see Fig. 2b), where numbers are rep- 12 resented as continuous values rather than discrete-token sequences. We compare this approach and observe 12 that our pipeline achieves improved precision and an expanded generalization capacity across evaluations. 12 Our study is an examination of the adaptability of LLMs to novel domains and an attempt to understand 13 how these powerful, semantically driven models can be repurposed and refined to gain a precise, metric 13 understanding of the 3D world. While our investigation is preliminary, our work payes the way for further 13

2 Related Work 14

endeavors to capitalize on the rapid advancements in LLMs. 13

Visual Program Induction. Visual program induction is a subfield of program synthesis that is focused 15 on recovering a graphics program from a given visual target (Gulwani et al., 2017). Graphics programs, also 15 known as procedural or symbolic programs, offer a concise, structured, and interpretable representation for 15 scenes and have garnered significant attention in the field – see Ritchie et al. (2023) for an in-depth overview. 15 Commonly employed program types include constructive-solid geometry (CSG) (Du et al., 2018; Kanja et al., 15 2020; Ren et al., 2022; Sharma et al., 2018a; Yu et al., 2022), computer-aided design (CAD) Ganin et al. (2018); Li et al. (2020a; 2022a); Seff et al. (2022); Xu et al. (2021), vector graphics (e.g., SVG) (Reddy et al., 2021a;b), and L-systems (Guo et al., 2020), as well as custom program domains (Ellis et al., 2018; Tian et al., 15 2019; Deng et al., 2022; Hu et al., 2022b). Program discovery can be achieved from simplified representations 15 of the same modality, such as 2D hand drawings or synthetic patterns (Št'ava et al., 2010; 2014; Sharma 15 et al., 2018a; Ellis et al., 2019; Riso et al., 2022; Ganeshan et al., 2023; Seff et al., 2022), as well as 3D 15 meshes and voxels (Ganeshan et al., 2023: Jones et al., 2022: Tian et al., 2019: Bokeloh et al., 2010: Willis 15 et al., 2021; Sharma et al., 2018a; Ellis et al., 2019). There have also been efforts in recovering 3D scenes 16 from natural 2D images using graphics programs (Mansinghka et al., 2013; Kulkarni et al., 2015; Wu et al., 2017; Yi et al., 2018; Mao et al., 2019; Liu et al., 2019; Li et al., 2020b; Gothoskar et al., 2021; Ganin et al., 15 2018: Kar et al., 2019: Devaranjan et al., 2020). Kulkarni et al. (2015) propose a probabilistic programming 15 language for representing arbitrary 2D/3D scenes, demonstrating preliminary results for analysis of faces. bodies, and objects. Wu et al. (2017) infer custom-designed markup code from images that can be easily 15 translated to renderer-friendly inputs. The work can handle scenes with a number of objects, but cannot 15 generalize beyond the training data distribution. In follow-up work, Yi et al. (2018) investigate how graphics 15 programs can be used for visual question answering (VQA). However, their scene reconstruction also struggles 15 with generalization problems, particularly to unseen attribute combinations. Liu et al. (2019) present a new 15 language for representing scenes, along with a hierarchical approach for inference. Meta-SIM (Kar et al., 15 2019; Devaranjan et al., 2020) uses probabilistic scene grammars to recover synthetic scenes from natural 15 images, which are then used to train a generative scene-synthesis model. Despite promising results, such 15 methods require special training data and complex modular architectures, and are difficult to generalize 15 beyond their training distribution. 15

Vision as Inverse Graphics. Dating back to Larry Roberts's Blocks-World thesis (Roberts, 1963), there has been a long history of work that treats computer vision as the inverse problem to computer graphics. Efforts have included estimating object pose (Lepetit et al., 2009; Tejani et al., 2014; Pavlakos et al., 2017; 15 Xiang et al., 2018; Wang et al., 2021b; 2019; 2021a; Ma et al., 2022; Labbé et al., 2020) and reconstructing 16

shape (Choy et al., 2016; Fan et al., 2017; Groueix et al., 2018; Mescheder et al., 2019; Wang et al., 2018; 16 Sitzmann et al., 2019: Park et al., 2019) from single images. Multi-object scenes have also been recovered 16 via geometric approaches (Gkioxari et al., 2019: Denninger & Triebel, 2020: Shin et al., 2019), but they 16 often overlook the semantics and interrelation between objects, hindering further reasoning. Holistic 3D-16 scene understanding takes the approach a step further by reconstructing individual objects together with 16 the scene layout. Early methods focus on estimating 3D bounding-box representations (Hedau et al., 2009; 15 Lee et al., 2009; Mallya & Lazebnik, 2015; Ren et al., 2017; Dasgupta et al., 2016), whereas more-recent 16 works emphasize the reconstruction of finer shapes (Zhang et al., 2021; Liu et al., 2022; Gkioxari et al., 2022) 16 along with instance segmentations (Kundu et al., 2022; Yao et al., 2018; Dahnert et al., 2021; Nie et al., 2020; Zhang et al., 2023b; Nie et al., 2023). Closely related are methods that perform CAD or mesh-model 16 retrieval followed by 6-DOF pose estimation of individual objects (Aubry et al., 2014; Bansal et al., 2016; 16 Lim et al., 2014; Tulsiani & Malik, 2015) or scenes (Izadinia et al., 2017; Huang et al., 2018; Salas-Moreno 16 et al., 2013; Kundu et al., 2018; Gümeli et al., 2022; Kuo et al., 2020; 2021; Engelmann et al., 2021). An alternative to detailed shape reconstruction is *primitive* reconstruction, where objects or scenes are explained 16 by a limited set of geometric primitives, offering a higher level of abstraction. This direction has been studied 16 extensively (Roberts, 1963; Binford, 1975; Hedau et al., 2009; Gupta et al., 2010a;b), and it is still actively 16 researched (van den Hengel et al., 2015; Tulsiani et al., 2017; Paschalidou et al., 2019; 2020; 2021; Deng 16 et al., 2020; Kluger et al., 2021; Monnier et al., 2023; Vavilala & Forsyth, 2023). While these works typically 16 produce accurate reconstructions, they involve complex pipelines with multiple modules and require special 16 training data, limiting generalization under distribution shifts. In contrast, we explore the use of LLMs as 16 a potentially simpler and more-generalizable solution to the inverse-graphics problem. 16 LLMs and 3D Understanding. Recent and concurrent efforts have explored the use of LLMs for 3D-17

LLMs and 3D Understanding. Recent and concurrent efforts have explored the use of LLMs for 3D-17 related tasks, including 3D question answering (Hong et al., 2023; Dwedari et al., 2023), navigation (Hong et al., 2023; Zhang et al., 2023a), text-to-3D (Sun et al., 2023), procedural model editing (Kodnongbua et al., 2023), and multi-modal representation learning (Xue et al., 2023; Hong et al., 2023). To the best of our knowledge, our work is the first to investigate the application of LLMs to inverse-graphics tasks.

3 Method 18

The goal of this work is to assess the efficacy of LLMs in inverse-graphics tasks. We frame the problem as that of estimating a graphics program from a single image (see Fig. 1) and fine-tune an LLM using a small, synthetic dataset. We begin by analyzing the advantages this approach offers over traditional approaches in 19 Sec. 3.1. Subsequently, we delineate the details of our methodology in Sec. 3.3. Finally, we elaborate on the design and motivation of the numeric head to enable precise metric reasoning in Sec. 3.4.

3.1 Traditional Neural Scene De-Rendering 20

Our approach builds upon the concept of neural scene de-rendering introduced by Wu et al. (2017). In this 21 framework, the goal is to develop a generalizable model capable of comprehensively understanding a scene 21 by estimating a graphics program executable by a renderer. NS-VQA (Yi et al., 2018) is representative of 21 this paradigm, where the task is addressed by decomposing the visual input using multiple modules with 21 task-specific visual inductive biases. The method includes several components: a region-proposal network 21 for object detection, a segmentation network for isolating the objects from the background, an attribute 21 network for classifying various discrete graphics attributes, and a localization network for predicting the 21 object's spatial location. Each network is independently trained in a supervised manner with a specific 21 objective, and their outputs are aggregated to produce a structured representation of the scene. 21

3.2 What Do LLMs Offer? 22

The broad success of LLMs can be largely attributed to their exceptional ability to generalize. Unlike 23 models that rely on task-specific inductive biases or well-crafted training objectives, LLMs (Brown et al., 23 2020; Radford et al., 2019; Touvron et al., 2023) perform proficiently across a variety of language tasks with 23

relatively minor design differences and a simple training approach. This success can be attributed to the scale of the models and the sets of in-the-wild data on which they are trained. 23

A particularly intriguing development in recent years has been the adaptation of LLMs to downstream tasks 24 through instruction-tuning (Chung et al., 2024; Wang et al., 2023; Chiang et al., 2023), where LLMs are 24 fine-tuned on a small set of curated task-specific training samples (e.g., 52K instruction-following examples 24 in Stanford Alpaca (Taori et al., 2023)). This suggests a paradigm shift from traditional approaches, where 24 generalization is often attained by scaling the amount of task-specific training data. LLMs are primarily 24 trained via an unsupervised next-token-prediction objective to perform language-completion tasks, thereby 24 unifying various natural language processing (NLP) tasks within a generic framework. Our research aims 24 to explore whether this generalized approach can be effectively extended to the task of scene de-rendering 24 while preserving their strong generalization capabilities. 24

3.3 Tuning LLMs for Inverse Graphics 25

While LLMs are traditionally trained to complete language-token sequences, VQA works (Alayrac et al., 2022; 26 Li et al., 2022b; Liu et al., 2023) have demonstrated that large pretrained vision transformers (Dosovitskiy 26 et al., 2021; Radford et al., 2021) can be efficiently adapted as visual tokenizers. Such works unify image 26 and language understanding, interleaving visual embeddings with language tokens for the LLM. In line with 26 this approach, we adopt a similar strategy, constructing an LLM capable of "seeing" the input image and 26 returning a structured code representation of the input scene. 26

In the subsequent paragraphs, we detail the base architecture, elucidate the process of vision-language alignment, and introduce our methodology for preparing synthetic data for visual instruction finetuning. A 27 high-level overview of our pipeline can be seen in Fig. 1. 27

Architecture. Our model is based on an instruction-tuned variant (Peng et al., 2023) of LLaMA-1 7B (Touvron et al., 2023) in conjunction with a frozen CLIP (Radford et al., 2021) vision encoder, serving as the visual tokenizer. We apply a learnable linear projection to link the vision embeddings with the word-embedding space of the LLM 28

Vision-Language Alignment. The linear vision-encoder projection is initially trained using the feature-alignment pre-training method from LLaVA (Liu et al., 2023). This training uses instructed to sequences constructed from image-caption pairs sourced from the Conceptual Captions dataset (CC3M) (Sharma et al., 2018b). The LLM receives the projected image embedding, followed by a randomly sampled directive tasking the model to describe the image and its corresponding caption. Throughout this stage, all model parameters remain fixed except for the learnable vision projector. To ensure the generality of our model, we refrain from additional instruction tuning following this initial feature alignment.

Training-Data Generation. CLEVR (Johnson et al., 2017) is a procedurally generated dataset of simple 30 objects on a plane. The primitives are assigned randomly sampled attributes such as shape (sphere, cube, and cylinder), size, color, material, and spatial pose. Shape, size, color, and material are discrete attributes, while pose is a continuous parameter specifying the object's location and orientation. The images from the sampled scenes are rendered using the Blender (2018) modeling software from its Python scripting APL 30 Our domain-specific language consists of add functions, facilitating the insertion of objects with specified attributes into the scene using Blender. See Fig. 1 for an example of the representation of a single object.

To train our model, we generate pairs of rendered images and their corresponding code, prompting the model 31 with the rendered image followed by the question, "What Python Blender code could be used to produce 31 the scene?". The model is then trained with a standard next-token prediction objective (Bengio et al., 2000), 31 aiming to maximize the conditional probability of the next token given the previous ones: 31

$$p(x) = \prod_{i=1}^{n} p(s_i|s_1, \dots s_{i-1}),$$
(1)

where s_i represents the *i*th token. Numbers are rendered with three decimal places in the text-based (tokenized) training data. We order the add statements front-to-back in the objective token sequence and shuffles the order of the object attributes. See Figs. S.2 to S.6 for complete examples of each task. 33

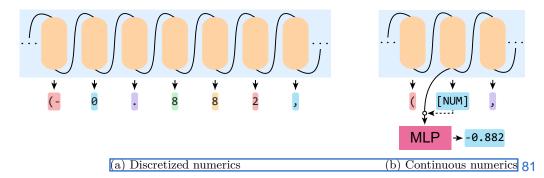

Figure 2: Numeric Head. (Sec. 3.4) Rather than producing digits as discrete tokens (a), we train our model to generate a [NUM] token when a number should be produced. The [NUM] token is used as a mask to signal the embedding should instead be passed through the numeric head, preserving the gradient (b). 42

Differences From Traditional Approaches. The framework presented in this study marks a departure from conventional approaches. Notably, the visual-encoding process does not include graphics-specific inductive biases in its design. It undergoes no training for intermediate vision tasks, such as object detection, segmentation, or attribute regression. The model operates solely on rendered images without access to 3D assets. Moreover, the supervised fine-tuning process employs a training objective not directly related to the physical representation of the scene. 34

We show in Sec. 4 that these departures do not impede performance or generalization capabilities compared with traditional approaches; in fact, they enhance them. Our experiments demonstrate a compositional-generalization ability without the need for tailor-made designs, surpassing the conventional approach by approximately 60% in OOD shape-recognition accuracy. 35

3.4 Precise Numeric Reasoning in LLMs 36

Graphics programming requires the precise estimation of continuous quantities such as location and ori- 43 entation, along with a comprehension of Euclidean space. This requirement extends beyond the coarse, 43 semantic-level spatial reasoning (e.g. "left." "in front of") for which LLMs are typically employed, in tasks 43 such as VQA (Antol et al., 2015). Estimating continuous values through character-based outputs essentially 43 transforms the task into a discrete, combinatorial challenge. In this loss space, prediction errors do not 43 reflect real metric distances – a ground truth value of '4' is considered as close to a prediction of '3' as it is 43 to '8,' highlighting the inherent limitations of this approach for tasks demanding high numerical precision. 43 To address this challenge, we introduce a *numeric head* tailored to enable continuous parameter estimation. 44 A visual representation of the numeric-head integration is depicted in Fig. 2b, contrasting with the discrete 44 text-based alternative. The module is implemented as a four-layer MLP that processes the final hidden-layer 44 output of the LLM and transforms it into a scalar value. To allow the LLM to discern between generating 44 numerical values or textual information, we designate a special token in the vocabulary – [NUM] – which 44 serves as a mask to indicate whether a number should be produced. During training, we apply an MSE loss 44 on each number in addition to the next-token prediction loss (Eq. (1)) used on the [NUM] token itself, 44 We systematically investigate the behavior of character-based and numeric IG-LLM variants for precise 45 spatial reasoning in Sec. 4.2. Our empirical findings support our intuition regarding the limitations of 45 the character-based output and demonstrate that the numeric head enables strong generalization when the 45 testing samples are OOD in parameter space. These differences are highlighted throughout our evaluation. 45

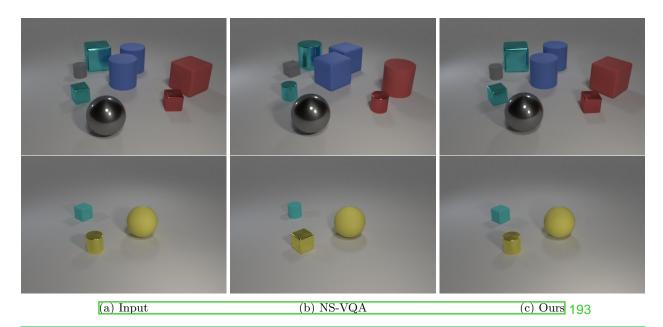

Figure 3: OOD CLEVR-CoGenT Samples. (Sec. 4.1) NS-VQA, with its modular design, fails to disentangle shape from color, while our framework is able to effectively generalize to OOD attribute combinations. See Fig. S.7 for additional samples.

4 Evaluations 46

To evaluate the ability of our proposed framework to generalize across distribution shifts, we design a number of focused evaluation settings. We conduct experiments on synthetic data in order to quantitatively analyze 55 model capability under controlled shifts. 55

4.1 Compositional Generalization on CLEVR 56

An extension to CLEVR, known as CLEVR-CoGenT (Johnson et al., 2017), serves as a benchmark for evaluating the *compositional*-generalization capabilities of VQA models. This benchmark assesses the model's ability to answer questions about scenes containing objects with unseen combinations of attributes. During training, the dataset is structured such that particular types of objects are only assigned specific combinations of attributes (e.g. blue cubes and red cylinders), while the testing data includes objects with attribute combinations not seen during training (e.g. red cubes and blue cylinders). We adapt this VQA dataset to our inverse-graphics problem domain, employing it for three primary purposes: 1) demonstrating that LLMs can effectively perform inverse graphics by testing on in-distribution (ID) data; 2) illustrating that LLMs exhibit robust compositional generalization to OOD data, while the baseline approach in NS-VQA (Yi et al., 57 2018) struggles in this setting; and 3) exploring the data-efficiency of our framework.

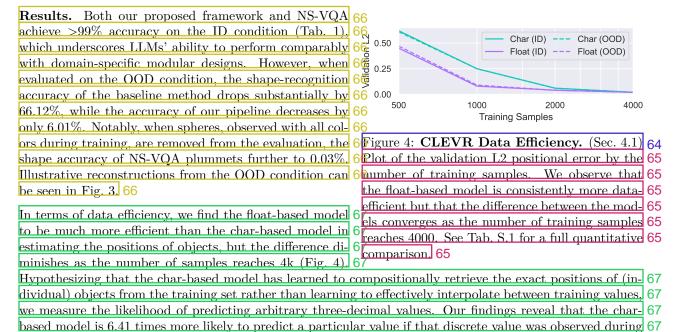

Setting. Following the setting of CLEVR-CoGenT, our training set consists of images of scenes containing objects with only a subset of possible attribute combinations (shape, size, material, and color). In the ID 58 condition, all cubes are rendered in gray, blue, brown, or yellow, and all cylinders are depicted in red, green, purple, or cyan. In contrast, in the OOD condition the color palettes of the shapes are swapped. Spheres are consistently depicted with all eight colors under both conditions. We train both our proposed framework and NS-VQA, our neural-scene de-rendering baseline, on 4k images from the ID condition and evaluate them on 1k images from both the ID and OOD conditions. We follow CLEVR and randomly apply their set of synonyms on the categorical attributes. 58

Evaluation Metrics. To evaluate attribute-recognition accuracy, we employ linear-sum assignment on pairwise Euclidean distances to match predicted and ground-truth objects. However, since attribute-recognition 62 accuracy does not account for missing or duplicated objects, we also evaluate the method's ability to produce 62

Table 1: CLEVR-CoGenT Results. (Sec. 4.1) While both our proposed framework and the baseline, 60 NS-VQA, and are able to achieve >99% accuracy on the ID condition, the baseline fails to generalize, with 60 its shape-recognition accuracy dropping by 66.12%. Color, Mat., and Shape represent respective accuracies 60 and ↑ indicates greater is better. 60

		ID			OOL	61
	Char	Float	NS-VQA	Char	Float	NS-VQA 61

accurate counts by computing the mean-absolute counting error between the predicted and ground-truth object sets across scenes (Count). 62

4.2 Numeric Parameter-Space Generalization 68

training. We further explore float-estimation dynamics in Sec. 4.2. 67

In this section, we investigate the addition of a numeric head and the ability of our framework to generalize 69 across parameter space. 69

4.2.1 2D Parameter Space 82

We begin by scrutinizing the framework's ability to generalize in 2D parameter space across range gaps. To accomplish this, we create a dataset comprising 10k images, each featuring a red dot on a white background. 83 During training, the model is shown images where the location of the dot is sampled from a sparse checker-83 board grid, as shown in Fig. 5a. During evaluation, the model is shown 1k images where the dot's location so uniformly sampled across the square; points lying outside the checkerboard are effectively OOD inputs. 83 Results. As shown in Fig. 5b, the char-based model exhibits significant overfitting to the training dis-84

tribution, consistently predicting dot locations restricted to the checkerboard distribution observed during training. In contrast, the float-based model is able to effectively generalize across parameter space, adapting

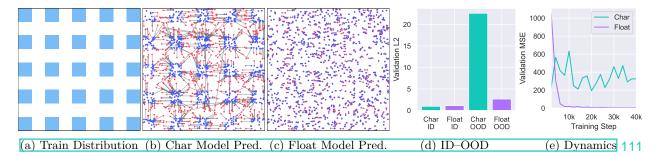

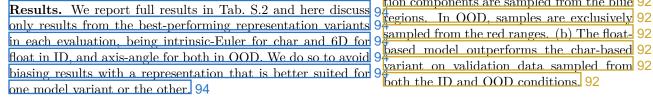

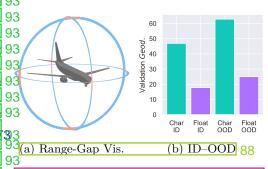

Figure 5: **2D Parameter-Space Generalization.** (Sec. 4.2.1) (a) Training positions are sampled from the 81 checkerboard. When evaluated on images with uniformly sampled positions, the char-based model fails to 81 generalize outside the training distribution (b) while the float-based model effectively interpolates samples 81 (c). Randomly-sampled testing locations are shown in red and the corresponding predictions in blue. (d) 81 shows that while both methods well-estimate samples from the ID condition, the char-based model struggles 81 to generalize, (e) shows a plot of the model's validation MSE as a function of the number of training steps, 81 We observe that the training of the float-based model is much smoother and converges quickly. 81

to the uniformly sampled testing distribution during evaluation (Fig. 5c). Although the float-based model 84 exhibits a slight positional bias toward predicting positions on the grid (as evidenced by the higher OOD 84 error), the disparity in the ID-OOD validation-L2 performance gap of the char-based model is 14 times 84 as high as that of the float-based model (Fig. 5d). Moreover, the validation MSE of the float-based model 84 converges quickly to near zero, while the error of the char-based model is much less stable over time (Fig. 5e), 84 suggesting that the float-based model learns smooth, low-dimensional representations of the space while the 84 char-based variant may not. 84

SO(3) Parameter Space 85 4.2.2

We continue our parameter-space evaluation within the more 93 complex task of SO(3)-pose estimation of orientable objects. 93 For this, we make use of five toy-airplane assets sourced from 93 Super-CLEVR (Li et al., 2023). We construct a training 93 dataset of 10k images of single planes at a fixed location and 93 sampled attributes identical to those in CLEVR. Extending the 93 range-gap setup used in Sec. 4.2.1, the airplanes are assigned 93 random extrinsic-Euler rotations, where the components are 93 sampled from ranges containing inserted gaps (e.g., [-\frac{\pi}{20}] \frac{1}{21}]. A visual depiction of this space is provided in Fig. 6a. with the training values exclusively sampled from the blue ranges. 93 During testing, we invert the gaps to assess OOD generaliza-9 Figure 6: SO(3) Range Gap. (Sec. 4.2.2) 91 tion. We evaluate performance across intrinsic-Euler, extrinsic-9 (a) Visualization of the SO(3) range-gap 92 Euler, axis-angle, and 6D (Zhou et al., 2019) representations, 93 sampling space. For training, Euler rota-92

tion components are sampled from the blue 92 9tegions. In OOD, samples are exclusively 92 based model outperforms the char-based 92

As depicted in Fig. 6b, the error of the char-based model is 2.64 times higher than that of the float-based 95 model when evaluated in-distribution. Upon testing in the OOD condition, the disparity is nearly consistent 95 at 2.52 times that observed in the ID scenario, with the ID-OOD gap of the char-based model being 2.21 times 95 that observed in the float-based variant. We attribute the superiority of the float-based model across both 95 conditions to the increased data dimensionality. Additionally, the lesser performance decline observed when 95

Figure 7: OOD Single-Object 6-DoF Samples. (Sec. 4.3.1) A sample 6-DoF reconstruction of real-world images. The model is finetuned with only Blender renderings of toy airplanes that have a white backdrop. 98 See Fig. S.10 for additional samples. 98

evaluating on the OOD training gaps further underscores the parameter-space efficiency of the float-based 95 model 95

4.3 6-DoF Pose Estimation 96

We examine the ability of our framework to scale in tackling a more challenging inverse-graphics task: that of 6-DoF-pose estimation. Our exploration begins with an evaluation on single-object images, encompassing both quantitative and qualitative assessments, where we illustrate the framework's ability to generalize across visual domain shifts. We subsequently extend the setting to include more-complex (albeit, synthetic) multiplicated scenes, demonstrating promising results for scene estimation, handling larger collections (>100) of diverse assets.

4.3.1 Single-Object 6-DoF 100

We first evaluate our framework's ability to scale to single-object 6-DoF pose estimation. The float- and 104 char-based models are assessed quantitatively using rendered images. 104

Setting. We extend the setting used in Sec. 4.2.2 but unfreeze the previously fixed 3D position and assign it a randomly sampled value. We expand the number of colors used in the dataset to 133¹ to better mulate the diversity observed in the real world. Differing from the previous setup, we fix the size of the objects due to the relative depth-scale ambiguity of the toy airplanes. To evaluate our framework's ability to scale beyond data-constrained scenarios, we render a training dataset of one-million images. Following the rotation-representation results of Sec. 4.2.2, we use the intrinsic-Euler representation for the char-based model and the 6D representation for the float-based model as their use led to the greatest ID performance.

Results. Tab. 2 illustrates that, under this non-data-constrained scenario, both model variants effectively capture the dynamics of the task The models both notably exhibit an order of magnitude lower positional 107 error than in the CLEVR setting, despite the addition of 3D orientation and an additional positional dimension, and achieve rotational error 28% of that observed in the ID portion of the SO(3) range-gap evaluation.

Ihttps://simple.wikipedia.org/wiki/List_of_Crayola_crayon_colors 23

Table 2: Single-Object 6-DoF Results. (Sec. 4.3.1) When evaluating on ID data in the one-million-sample single-object 6-DoF eval, we observe little difference between models; both well-capture the distribution. 101 Geod. represents geodesic distance in degrees. 101

	\downarrow L2	↓Geod.	↑Color	↑Mat.	↑Shape 146
Char	0.02	5.03	79.10	99.00	99.80 102
Float	0.04	6.18	81.90	99.00	100.00 102

Figure 8: OOD ShapeNet 6-DoF Samples. (Sec. 4.3.2) Two sample reconstructions from the OOD ShapeNet 6-Dof pose-estimation experiment. Left to right: input, output. We evaluate on assets not shown during training, with out-of-distribution textures. See Fig. S.9 for additional samples.

This reinforces the earlier observation from the CLEVR data-efficiency evaluation that, given sufficient data, 107 the model variants exhibit a similar performance ceiling. Still, neither achieves the level of precision necessary to be directly constrained by the three-decimal-place discretization applied to numeric quantities throughout 107 the evaluations nor the 16-bit training precision in the case of the float-based model. See Appendix A for 107 further training details.

As part of our evaluation, we also qualitatively examine the ability of the model to transfer from the renders of toy planes with a solid-white background, on which it was fine-tuned, to estimating the pose and attributes to planes in real-world images. We provide qualitative samples of our model's generalization to such images to the provide qualitative samples of our model's generalization to such images to the provide qualitative samples of our model's generalization to such images to the planes in Fig. 7. We observe encouraging generalization across the majority of images tested, despite the lack of augmentation or domain-specific inductive bias applied during the training process. However, it is difficult to quantitatively evaluate such model performance due to a lack of paired real-world data in line with our compositional task. As a proxy for such an evaluation, we introduce a synthetic setting in Sec. 4.3.2 to 108 quantitatively evaluate the ability of our framework to generalize across visual domains.

4.3.2 Scene-Level 6-DoF 109

In this section, we explore the scalability of our framework to scene-level 6-DoF-pose estimation, featuring 115 3-5 objects per scene and a much-expanded array of assets. This experiment not only assesses performance 115 under more-challenging conditions, but also enables a quantitative evaluation on the framework's ability to 115 generalize to scenes with OOD visual appearance. 115

Setting. We construct an expanded CLEVR-like image—scene dataset, incorporating objects sourced from ShapeNet (Chang et al., 2015). The dataset comprises 56 chair types, 35 sofa types, and 47 table types.

Table 3: ShapeNet 6-DoF Results. (Sec. 4.3.2) The float-based model outperforms the char-based variant across all evaluations. *Chamf.* represents the Chamfer distance between the ground-truth and estimated 111 scenes. *Cat.* represents category accuracy (sofa, chair, table). 111

	_					
	I	D	00	D-T	OOD	<u>-T+S</u> 101

↓Chamf.	0.45	0.22	1.17	0.57	14.63	2.58 112

We remove the size and material attributes used in CLEVR, but employ the expanded color set used in 116
Sec. 4.3.1 to randomly color the objects. After doing so, the total number of possible combinations of
attributes is 191-fold that used in the CLEVR-CoGenT experiment. Differing from previous evaluations,
we also vary the pitch of the camera and the radius of its arc, but maintain a fixed camera focal point. 116
Returning from the million-image single-object 6-DoF evaluation to a relatively data-constrained setting, 116
we render 10k training images and evaluate the framework on three conditions, each with 1K images: (1) 116
ID, which matches the training distribution of scenes with solid-colored objects; (2) OOD texture (OOD-T), 116
where the same object assets are used as in ID but the objects are rendered with original ShapeNet textures 116
instead of the randomly assigned solid colors; and (3) OOD encompassing both unseen objects and original 116
ShapeNet textures (OOD-T+S). We use this to emulate the distribution shift of modeling real-world scenes, 116
while facilitating quantitative evaluation. 116
Results. We observe that both approaches scale to the task, though the float-based model outperforms – or
ties with – the char-based variant across evaluations (Tab. 3). This disparity is emphasized in the OOD-T+S
setting where scene-level chamfer distance of the char-based model jumps from being approximately twice 117
that of the float-based variant in the ID and OOD-T evaluations to being 5.67 times as much. 117
There is a decrease in performance observed when stepping to the OOD-T setting, which is most-strongly 118
observed in the count error (x8 for both) and the shape-recognition accuracy (-20.49% in char and -15.05% in
float). We empirically attribute this to the model occasionally explaining some multi-color textured objects 118
using a composition of multiple, solid-color assets. Quantitatively supporting this, the performance decrease 118
is not as strongly reflected in scene-level chamfer distance ($x2.6$ for both). 118
See Fig. 8 for samples reconstructions from OOD-T+S and Fig. S.8 for samples from the ID setting. We
additionally test our model on real-world samples, but find that it fails to consistently generalize (Fig. S.1). 119
We attribute this failure partially to limitations in the camera-position training distribution. 119

5 Discussion and Limitations ₁₂₀

Through our investigation, we demonstrated the ability of LLMs to facilitate inverse-graphics tasks across 12
a variety of domain shifts, albeit within controlled settings. In designing targeted evaluations to analyze 12
the model's generalization ability, our goal was to lay the groundwork necessary for future advancements. 12
However, scaling up these models to metrically reconstruct complex real-world scenes will undoubtedly pose 12
additional challenges. 121
The primary limitation of our approach lies in that its expressiveness is constrained by the expressiveness of
the training-data-generation framework. We demonstrated its ability to learn to compositionally disentangle 12
images of scenes into constituent elements, reconstructing scenes under distribution shifts. However, repro-
ducing scenes as text, it can reconstruct scenes containing unknown objects in OOD configurations, but it
does so in terms of the objects – and language – it is trained with. If it does not know the name of asset 12
chairs_0055, it will not be able to use it. Even if the model produces the name of a new color or shape from 12
outside of the training data, the graphics engine rendering the LLM output must have an understanding of 12
it in order to apply it. 122
In contrast, the generality of our approach, which doesn't incorporate special task-specific inductive biases, 12
allows it to scale with the diversity of the training data or the expressivity of the code format. Future work
may explore more-scalable training-data generators or integrate self-supervision techniques to enable learning 12
from unlabeled images. While we employ a relatively straightforward object-centric code representation 12
across experiments for simplicity, more-expressive scene representations should also be explored. 123
Our evaluation scenes feature only minor object occlusions and are relatively simple. While a generic 12
next-token objective paired with MSE float supervision sufficed for these scenarios, addressing harder-to-
disentangle scenes may require a trade-off between generality and inductive bias, to incorporate additional 12
supervision. 124

6 Conclusion ₁₂₅

In this work, we investigated the ability of LLMs to solve inverse-graphics challenges. Introducing the Inverse-	126
Graphics Large-Language-Model (IG-LLM) framework, we demonstrated that the broad generalization and	126
reasoning capabilities of LLMs can be harnessed to facilitate inverse-graphics tasks. Through extensive	126
evaluation, we assessed the model's capacity to generalize out-of-domain, revealing its ability to abstract	126
scene elements compositionally. We additionally explored the integration of a numeric head to adapt LLMs	126
for continuous metric-value estimation, providing enhanced generalization and smoother training dynamics.	126
Our quantitative analyses demonstrate its ability to generalize compositionally (Sec. 4.1), in parameter space	126
(Sec. 4.2), and across visual domains (Sec. 4.3). Our investigation demonstrates the ability of IG-LLM to	126
leverage the general knowledge of LLMs in solving inverse-graphics problems, opening a new avenue for	126
research. 126

A Further Training Details 129

We finetune the LLaMA 1-based Vicuna 1.3 model ² with LoRA (Hu et al., 2022a). We use the HuggingFace 130
Transformers and PEFT libraries, along with DeepSpeed ZeRO-2 (Rajbhandari et al., 2020). In all exper-
iments, we use a lora_r of 128, a lora_alpha of 256, a LoRA learning rate of 2e-05, a linear projector 130
learning rate of 2e-05, a numeric head learning rate of 2e-04, and a cosine learning-rate schedule. All models
are trained with an effective batch size of 32 with bfloat16 mixed-precision training. Both the cross-entropy 130
next-token-prediction and mean-square-error losses are given a weight of 1. 130
The models for the CLEVR and parameter-space generalization experiments are trained for 40k steps. The 131 6-DoF pose-estimation models are trained for 200k steps. 131
We use the frozen CLIP visual tokenizer from ³ . This CLIP variant has an input size of 336x336 pixels. 132
For the CLEVR evaluation, we render images at the original size of 480x320 to ensure compatibility with 132
NS-VQA, but pad and resize them for use with our model. For the remaining evaluations we directly render 132
images at a resolution of 336x336. 132

We employ greedy token sampling across evaluations. 133

B Further CLEVR Data-Generation Details 134

The original CLEVR dataset is rendered with random positional jitter in both the lights and camera. This information is not recorded in the public dataset, so we re-render CLEVR-CoGenT with a fixed camera position, but maintain the randomness in the lighting 135

C Further Numeric-Head Details 136

Our numeric head is composed of a tanh layer, followed by a linear layer, a GELU activation, and a final 13
linear projection. The final LLaMA hidden state is passed through an RMS norm (Zhang & Sennrich, 2019) 13
before it is shared between the token head and numeric head, which re-scales but does not re-center the 13
embedding. 137
During training, the locations of these tokens in the ground-truth sequence are known so they can be masked 138
to apply the MSE loss. During sampling, the position of these tokens is not pre-known and dependent on the 138
generated sequence. We first generate the token-only sequence and then substitute the estimated numbers 138
back in with a second pass. 138

Figure S.1: Real-World ShapeNet 6-DoF Samples. (Sec. 4.3.2) Real-world sample reconstructions from the ShapeNet 6-Dof pose-estimation experiment. We observe that the model is sensitive to OOD camera configurations. During data generation, the camera is assigned a random pitch and radius, with its optical axis fixed passing through the global origin. As such, we find that the model learns the bias and is limited by the expressivity of the training-data-generation framework, and, while it effectively interpolates values, it struggles to extrapolate outside of the camera configurations on which it was trained on. We observe that the model is still, however, often able to identify the first few most-salient objects in the scene and produce meaningful assets (the first two in each of these samples being the rightmost chair then the table) before attempting to explain background features. 140
